The Science of Biology

ELEVENTH EDITION

SADAVA • HILLIS • HELLER • HACKER

Life

The Science of Biology

ELEVENTH EDITION

SADAVA • HILLIS • HELLER • HACKER

On the Cover

The cover depicts an extraordinary sight of coordinated movement-or murmuration-of a flock of starlings in response to a potential predator (a hawk). Individual birds coordinate their flight by sending, receiving, and processing signals from their immediate neighbors, although the exact processes that allow a flock of starlings to respond in almost perfect unison are still unknown. Murmuration is one of the most visible and beautiful examples of a critical transition, in which small perturbations to a system result in major transformations. Such critical transitions are important in many areas of biology, from the actions of individual proteins and cells to the behavior of flocks of birds.

A stunning video of the event is at

Life The Science of Biology

A Note from the Authors

Biology inspires wonder. The image of the flock of starlings on our cover shows an astonishing behavior known as murmuration—mesmerizing patterns that emerge out of thousands of birds flying in unison. This fascinating behavior is an example of what motivates biologists to study the complexities of life.

Biology is dynamic. It is constantly changing as new insights lead to new ideas and new tools to test those ideas. Think of the use of drones and satellites to photograph penguin populations in Antarctica. Think of the developments in biological imaging and computation. Think of genome sequencing and its effect on our understanding of everything from human diseases to the tree of life. Think of the use of ice cores to understand past global climate.

Biology is a system. Biological systems are made up of different levels of organization—from molecules to ecosystems—that are interconnected and complex. Biologists are beginning to use integrated approaches to understand the complex properties of biological systems.

Biology is life. We face many challenges as humans including emerging diseases, feeding people in a sustainable way, population growth, degradation of natural systems, and climate change. We understand that humans are integrally connected to and dependent on all life on Earth.

Our goal—and challenge—in writing *Life* is to engage students in all these aspects of biology by motivating learning through active discovery. We focus on key concepts and contemporary examples that provide a foundation for further study. We have consulted and collaborated with faculty, students, and experts in the fields of biology and education. As you will see in the next several pages, in this, our Eleventh Edition, we engage students by explaining how biology affects their daily lives and how new knowledge is discovered. To help students master the concepts and principles, we introduce a number of new active learning activities.

Please read on.

The Vision of Life: The Science of Biology

With roots 10 editions deep, the Eleventh Edition blends carefully reviewed content and an emphasis on experiments with a contemporary approach to active learning. Throughout, we focus on three driving themes:

***Life* is ENGAGING**

We want students to come away from the introductory biology course with a sense of wonder and an ability to pursue biological questions. To that end, we keep the writing lively, the examples modern and exciting, and the emphasis on how we know what we know.

To help students engage with the course, an **Investigating Life** thread weaves through each chapter. Each individual part of the thread appeals to students, inspires them to ask questions, and keeps them wanting to know, “What next?” The beauty of the thread is that it gives students an authentic scientific experience beyond just reading about someone’s research results.

***Life* is ACTIVE**

With the help of the Advisory Board, we’ve developed a series of pedagogical features that integrate tools for instructors with those for student independent study. Students work their way toward real understanding of biological principles. We don’t just ask them to memorize information—we invite them to actively participate in the process of discovery.

For instructors wanting to make active learning a part of their classroom, we’ve created an **Active Learning Guide**, with start-up material, ideas, and a complete guide to all the *Life* activities that are ready to add to your in-class repertoire.

***Life* is FOCUSED ON SKILLS**

We want students to feel comfortable as they learn to manipulate and interpret data. The various types of problem-solving exercises in *Life* help them develop practical, analytical, and quantitative skills—skills that will benefit them whether they continue in biology or not. Exercises vary in skill level, type, and approach, with answers in the back of the book.

The response to our **Work with the Data** boxes has been so consistently positive that we now include at least one in every chapter. This feature asks students to analyze data from original scientific experiments, and includes questions in the text plus, now, a corresponding set of alternative exercises online in LaunchPad. We also provide an appendix, **Making Sense of Data: A Statistics Primer**, to help students prepare for the quantitative work they’ll be doing.

Experience *Life* through LAUNCHPAD

With this edition’s **LaunchPad**, *Life* is more than ever a truly integrated text/media resource. LaunchPad gives students everything they need to prepare for class and exams, while giving instructors everything they need to set up a course, customize the content, craft presentations, assign homework, assess students, and guide the progress of individuals and the class as a whole.

“**What makes this book stand out** most among the competition is the way in which there is a continued sense of reinforcement for novice learners.”

—Claudette Davis, George Mason University

Life is **ENGAGING**

Investigating Life

The **Investigating Life** thread begins every chapter with a fascinating real-life story emerging from actual research. The story concludes with an **Opening Question** that is explored throughout the chapter's Investigating Life thread. By the end of the chapter, students should be able to understand the answer to the Opening Question.

investigatinglife

How Aspirin Works

Despite suffering from the “ague,” the Reverend Edward Stone went walking in the English countryside. Feverish, tired, with aching muscles and joints, he came across a willow tree. Although apparently unaware that many ancient healers used willow bark extracts to reduce fever, the clergyman knew of the tradition of natural remedies for various diseases. The willow reminded him of the bitter extracts from the bark of South American trees then being sold (at high prices) to treat fevers.

irritated the digestive system. In the late 1890s, the chemical company Bayer synthesized a milder yet effective form, acetylsalicylic acid, which it marketed. The new medicine's success launched Bayer to prominence as a pharmaceutical company, a position it holds today.

In the 1960s and 1970s, aspirin use declined when other pain-reducing medications became available. But over this same time, clinical studies revealed use for aspirin: it is an effective anticoagulant, preventing heart attacks and strokes caused by blood clots. Many people take a daily low dose of aspirin as a preventive measure against clotting disorders.

Fever, joint pain, headache, blood clots: What symptoms have in common? They all are mediated by acid products called prostaglandins and molecules derived from them. Salicylic acid blocks the synthesis of prostaglandin. The biochemical mechanism by which it works was described in 1971. As we will see, analyzing this mechanism requires an understanding of enzyme function—two subjects of this chapter.

Salicylic acid blocks the synthesis of prostaglandin. The biochemical mechanism by which it works was described in 1971. As we will see, analyzing this mechanism requires an understanding of enzyme function—two subjects of this chapter.

How Do Anti-Inflammatory Drugs Work as Enzyme Inhibitors?

experiment

Original Papers: Vane, J. R. 1971. Inhibition of prostaglandin synthesis as a mechanism of action of aspirin-like drugs. *Nature* 231: 232–235. Smith, J. B. and A. L. Wells. 1971. Aspirin selectively inhibits prostaglandin production in human platelets. *Nature* 231: 235–238.

The opening story in this chapter describes how willow bark, the source of what became aspirin, is a centuries-old remedy for pain and inflammation. Until the late twentieth century, it was assumed that aspirin acted directly on the nervous system. Working at England's Royal College of Surgeons, a group led by John Vane showed that aspirin acts instead as an inhibitor of the enzymatic reaction that produces prostaglandin (PG), a fatty acid derivative important in inflammation.

HYPOTHESIS Aspirin acts as an anti-inflammatory drug by inhibiting an enzyme that catalyzes prostaglandin synthesis.

METHOD

CONCLUSION In both animal and human cells, aspirin blocks the synthesis of the pro-inflammatory molecule, prostaglandin, in test tube experiments.

work with the data

For his discovery of the mechanism by which aspirin relieves pain, John Vane was awarded the Nobel Prize and knighted by Queen Elizabeth II. Key to the experiments was the assumption that enzyme activity and mechanism are the same outside the organism as they are inside. In the lab, if given its substrate and the same set of environmental conditions as in the cytoplasm, an enzyme will catalyze production of its product.

QUESTIONS

1. In the first set of experiments, lung tissue from guinea pigs was broken up to form a cell-free extract (homogenate). The substrate, arachidonic acid, was added to the extract, and after 30 min the amount of prostaglandin (PG) was measured. The results are shown in Table A. Plot PG synthesis versus aspirin concentration. What can you conclude?
2. A similar set of experiments was performed on human platelets (membrane-bound cell fragments derived from white blood cells). These cells are known to produce PG by the same enzyme mechanism as lung tissue under certain environmental conditions. The results are shown in Table B. What can you conclude from these results and about the generalizability of your conclusion from Question 1?

Table A

Aspirin concentration (μg/mL)	PG synthesis (ng)
0	220
1	172
2	136
10	99
50	33
80	0

Table B

Aspirin concentration (μg/mL)	PG synthesis (ng)
0	53
0.01	48
0.1	35
1	18
10	7

3. In a third set of experiments, platelets were isolated from human volunteers and their ability to make PG was measured (no aspirin present). Then these people were given a clinically effective dose of aspirin, and after a short period their platelets were isolated and PG synthesis measured (again, no aspirin in the test tube experiments). The results from these people are shown in Table C. How do these data either reinforce or refute your conclusion from Questions 1 and 2?

Table C

Individual	Prostaglandin synthesis (ng)	
	Before aspirin	After aspirin
1	160	16
2	108	5
3	103	20

A similar work with the data exercise may be assigned in LaunchPad.

Experiment & Work with the Data

The chapter continually returns to the opening story and question: the **Experiment** describes the original research behind the story and the **Work with the Data** gives students the opportunity to analyze research results for themselves. Work with the Data includes questions in the book and an additional corresponding exercise online and assignable in LaunchPad.

The **Investigating Life** thread provides a consistent pathway through each chapter that engages students from the first page (**Opening Story**), through the body of the chapter (**Experiment, Work with the Data**), to the last page (**Future Directions**). Through this emphasis on real experiments and data analysis, these learning tools show students how the concepts they're learning apply to the real world.

Answer to Opening Question and Future Directions

As the final piece of the Investigating Life thread, the **Opening Question**, which students have been considering throughout the whole chapter, is restated and the answer is explained in full detail. The final **Future Directions** section explores new questions and research opportunities that the chapter content leads to, setting the stage for students to consider how the textbook material matters in their lives.

QA How do anti-inflammatory drugs work as enzyme inhibitors?

Go into a drugstore or watch ads on TV, and it becomes obvious that there are many drugs that alleviate pain. Like aspirin, many of them target the prostaglandin pathway for inflammation. John Vane's research and later work showed that aspirin irreversibly inhibits the enzyme COX. But it turns out that there are two forms of COX, called COX-1 and COX-2, and there are several kinds of prostaglandins. COX-1 catalyzes the production of protective prostaglandins that are involved with blood clotting (which is why people take aspirin to prevent future heart attacks due to blood clots) and the integrity of the lining of the stomach. COX-2 catalyzes production of prostaglandins involved with inflammation and associated pain. Aspirin inhibits both COX-1 and COX-2. So it is not surprising that people are advised to go easy on aspirin: it may block pain, but its use can lead to stomach upsets and an inability to clot blood after a wound. Knowledge of aspirin's limitations has led to a search for inhibitors of COX-2 only. Most of them are competitive inhibitors. How would this affect how often you need to take the drug? Look up one of these drugs and read the description of how it works.

Future directions

As details at the atomic level of the binding of enzymes to substrates are worked out, biologists use the data to try to predict which substrates might bind to which enzymes. An important consideration in binding is ΔG ; the less positive this parameter, the more likely binding will occur. Factors such as ionic attractions and van der Waals forces contribute to the ΔG of binding. These factors are also important in the binding of proteins to nonsubstrate molecules, including other proteins and RNA. Indeed, it is becoming apparent that in general a protein in the cell does not exist in isolation, but is bound to something(s) else. If the protein is an enzyme, its substrate binding must be its most preferred partner. Understanding all the possible molecular interactions will result in a deeper understanding of what really goes on at the chemical level inside the cell.

Media Links

Throughout the chapter, **Media Links** prompt students to go online for video clips, animations, activities, and simulations that correspond to what they're reading. All of these items can be assigned in LaunchPad, and most are accompanied by assessments.

Media Clip 32.5: Komodo Dragons Bring Down Prey

Textbook Reference: Key Concept 32.4 Life on Land Contributed to Vertebrate Diver

in  LaunchPad

Most lizards are insectivores, although some are herbivores and a few prey on other vertebrates. Most lizards walk on four limbs (Figure 32.21B), although limblessness has evolved repeatedly among the lizards, especially in burrowing and grassland species. The largest lizard is the predaceous Komodo dragon of the East Indies, which grows as long as 3 meters and can weigh more than 150 kilograms.

Media Clip 32.5 Komodo Dragons Bring Down Prey
www.Life11e.com/mc32.5

We have developed a series of learning tools under the guidance of an Advisory Board of 19 experts in science education and pedagogy. These features are woven into the chapters so seamlessly that **active learning** is the natural result. All of these features are aligned to the new Learning Outcomes, giving students a clear expectation of what they need to learn.

Focus Your Learning

Each chapter is now organized around Key Concepts. **Focus Your Learning** statements zero in on the essential ideas in each Key Concept. These statements guide students in their reading and prepare them for the upcoming Recaps and Apply What You've Learned exercise.

Recaps with Learning Outcomes

Recaps summarize each section and include related **Learning Outcomes** and thought-provoking questions (with answers in the back of the book). Learning Outcomes are aligned with the section's Focus Your Learning statements, and they tell students how to show that they've mastered the material. The questions that follow are aligned with and reinforce the Learning Outcomes. This alignment helps students self-assess whether they should review the section or continue reading.

NEW

key concept

21.2

Phylogeny Can Be Reconstructed from Traits of Organisms

To illustrate how a phylogenetic tree is constructed, consider the eight vertebrate animals listed in **Table 21.1**: lamprey, perch, salamander, lizard, crocodile, pigeon, mouse, and chimpanzee. We will initially assume that any given derived trait arose only once during the evolution of these animals (that is, there has been no convergent evolution), and that no derived traits were lost from any of the descendant groups (there has been no evolutionary reversal). For simplicity, we have selected traits that are either present (+) or absent (-).

focus your learning

- Modern phylogenetic methods employ the principle of parsimony and mathematical models (when appropriate) to analyze morphological, developmental, paleontological, behavioral, and molecular data.

NEW

21.2 recap

Phylogenetic trees can be constructed by using the parsimony principle to find the simplest explanation for phylogenetic data. Maximum likelihood methods incorporate more explicit mathematical models of evolutionary change to reconstruct evolutionary history.

learning outcomes

You should be able to:

- Analyze a phylogenetic tree to identify synapomorphies, homoplasies, and relationships among taxa.
- Reconstruct a phylogenetic tree from a data matrix of characters.

The matrix at right supplies data for seven land plants and an outgroup: an aquatic plant known as a stonewort. Each trait is scored as either present (+) or absent (-) in each of the plants. Use this data matrix to reconstruct the phylogeny of land plants and answer the questions that follow.

Taxon	Protected embryos	True roots	Persistently green sporophyte	Vascular cells	Stomata	Megaphylls (true leaves)	Seeds
Stonewort (outgroup)	-	-	-	-	-	-	-
Liverwort	+	-	-	-	-	-	-
Pine tree	+	+	+	+	+	+	+
Bracken fern	+	+	+	+	+	+	-
Club moss	+	+	+	+	+	-	-
Sphagnum moss	+	-	-	-	+	-	-
Hornwort	+	-	+	-	+	-	-
Sunflower	+	+	+	+	+	+	+

- Which two of these taxa are most closely related?
- Plants that produce seeds are known as seed plants. What is the sister group to the seed plants among these taxa?
- Which two traits evolved along the same branch of your reconstructed phylogeny?
- Are there any homoplasies in your reconstructed phylogeny?

Simulations

Forty interactive **simulations** put the controls in students' hands and give them the opportunity to learn by doing. Topics include:

- Lipid Bilayer Composition
- Genetic Drift
- Visual Receptive Fields
- Island Biogeography
- Population Growth

Life, Eleventh Edition features a significantly increased number of simulations compared to the previous edition.

Please log in to LaunchPad to review the entire library of simulations.

Apply What You've Learned

Chapters conclude with an exercise that challenges students to put their newly acquired knowledge into action. The exercise presents a summary of research that is relevant to the chapter material followed by questions that, like Recap questions, align to the relevant Focus Your Learning statements, which are listed at the start of the exercise. Answers are in the back

of the book.

ACTIVITY 21.2: PHYLOGENY AND MOLECULAR EVOLUTION SIMULATION

NEW

Apply What You've Learned

Review

- 35.1** Plants receiving insufficient quantities of essential elements can be evaluated by observing symptomatic changes in physical features and/or growth.
- 35.1** Experiments using hydroponic growth conditions have allowed scientists to determine the essential elements plants need for growth.

Original Paper: Brown, P. H., R. M. Welch and E. E. Cary. 1987. Nickel: A micronutrient essential for higher plants. *Plant Physiology* 85: 801–803.

Both barley and wheat are cereal crops used for feeding humans and livestock, and the two have many similarities. Because of its characteristics when fermented, however, barley is favored over wheat for beer making. When you consider how much beer is brewed around the world, it's no wonder that researchers have spent considerable effort looking for ways to optimize barley growth.

Optimizing growth of any crop can be accomplished if the crop's nutritional requirements are known. In the case of barley, one research group investigated the element nickel as a possible essential micronutrient. Earlier studies where a single generation of plants was grown without Ni indicated that it was not a mineral requirement. They began by creating a stock growth solution containing extremely low amounts of nickel ions (less than 30 nanograms per liter [ng/L]). Then they divided this stock solution into three containers and added nickel sulfate (NiSO_4) to two of these. This step produced supplemented concentrations of 0, 0.6, and 1.0 micromolar (μM) nickel sulfate in the three final

Next, one portion of the seeds from each group was analyzed for nickel content. The other portion from each group was placed in nickel-free growth medium and tested for germination. The graph below shows seed germination success plotted against nickel content of the same seeds.

Questions

1. The researchers concluded that nickel is an essential micronutrient of barley. Do you agree with their conclusion? Explain your answer.
2. Analyze the data about the mass and number of seeds produced by the third-generation barley plants. What conclusion can you draw from these data? Is this consistent with your answer to Question 1 above? Explain.

Encouraging students to be active when they work with the book on their own is just the beginning. We are committed to active learning in any setting, including in the classroom, for any teacher who wants to try it. Perhaps the most powerful new tools for instructors in this edition are the **Active Learning Guide** and accompanying set of **Active Learning Modules and Exercises**.

Active Learning Modules

The new **Active Learning Modules** provide everything an instructor needs to successfully implement an active approach to teaching key topics. Each module includes many resources,

including:

- Pre-class video specifically created for the module
- Pre-quiz and post-quiz
- Handout for in-class work
- Detailed in-class exercise
- Detailed instructor's guide

These modules are easy to implement and are a great way to add more active learning to the classroom.

NEW

Transpiration-Cohesion-Tension Theory

Water potential ↑
Lower
Higher

Movement of water depends on:

- 1) the chemical properties of water
- 2) a gradient in water potential
- 3) avoiding cavitation

The last in this list is cavitation, which is the primary threat to the movement of water within xylem vessels.

ACTIVE LEARNING MODULE IN-CLASS EXERCISE SLIDES

“A lot of books try to sell their active learning focus, but this one actually **follows through in a meaningful way.**”

— Carly Jordan, George Washington University

The **Active Learning Guide** provides extensive resources and support for implementing active learning techniques in the classroom. This all-new guide provides instructors with a thorough introduction to the concepts, techniques, and benefits of active learning, along with chapter-by-chapter guidance on teaching using the many active learning resources we provide for *Life*, Eleventh Edition.

Part 1: Introduction to Active Learning

- What is active learning?
- Designing your course for active learning
- Using active learning in the classroom
- How to implement *Life*'s resources

Part 2: Chapter-by-Chapter Guidance

Each Active Learning Guide chapter contains:

- Overview of the textbook chapter
- The student resources available in LaunchPad for the chapter, with descriptions
- Specific concepts/content that are particularly well-suited to active learning techniques
- The chapter's Active Learning Exercises and how to integrate them into class sessions
- The relevant Active Learning Modules (if applicable) and how to integrate them into the course
- Suggestions for additional active learning opportunities
- Links to specific additional online resources

Part 3: Appendices

- Guide to Using Learning Standards in Teaching and Course Development

- Overview of Bloom's Taxonomy

'This textbook works well with any teaching style.... It is a great tool to help instructors **transform their classroom into an active learning environment**'.

—Robert Osuna, University at Albany, State University of New York

"The active learning modules included with this text **take the 'fear factor' out of active learning**".

—Candice Damiani, University of Pittsburgh

Life is FOCUSED ON SKILLS

Life has long been recognized for bringing quantitative analysis and critical thinking to the forefront of the introductory biology course. The new edition allows for more hands-on experience than ever with data manipulation skills, both in the book and in LaunchPad.

Work with the Data

In the **Work with the Data** exercises, students analyze the results of an original scientific experiment, then work through a series of questions. In response to overwhelmingly positive feedback, the new edition includes at least one Work with the Data box in each chapter

work with the data

Donald Levin of the University of Texas proposed that *Phlox drummondii* has red flowers only in locations where it is sympatric with pink-flowered *P. cuspidata* because having red flowers decreases interspecific hybridization. To test this hypothesis, Levin introduced equal numbers of red- and pink-flowered *P. drummondii* individuals into an area with many pink-flowered *P. cuspidata*. At the end of the flowering season, he assessed the genetic composition of the seeds produced by *P. drummondii*. The results are shown in the table below.

Morph (flower color)	Number of seeds (progeny)		
	<i>P. drummondii</i>	Hybrid	Total
Red	181 (87%)	27 (13%)	208
Pink	86 (62%)	53 (38%)	139

QUESTIONS

1. Check the 95% confidence intervals for the proportion of hybrid seeds in red- and pink-flowered *P. drummondii* in the graph in the Results of the experiment. There are many websites available for calculating confidence intervals; a good one is the Vassar College statistical computation site, VassarStats.net. You can go to this site and select "Proportions" from the left-hand menu, then select "The Confidence Interval of a Proportion." What are the numerical values of the 95% confidence intervals?

Online Companion Exercises

For additional practice, every Work with the Data exercise has a corresponding **Online Companion** in LaunchPad, addressing the same skills as its in-book equivalent.

NEW

Ch. 22 Work with the Data Online Companion Exercise: Flower Color Reinforces a Reproductive Barrier in Phlox

This exercise is a companion to the Investigating Life: Work with the Data exercise on p. 479.

Questions

[Edit questions](#) [Print](#)

1 | Ch. 22 Wwtd Question 1

[Collapse](#) [Edit](#) [Remove](#)

Donald Levin of the University of Texas proposed that *Phlox drummondii* has red flowers only in locations where it is sympatric with pink-flowered *P. cuspidata* because having red flowers decreases interspecific hybridization. To test this hypothesis, Levin introduced equal numbers of red- and pink-flowered *P. drummondii* individuals into an area with many pink-flowered *P. cuspidata*. At the end of the flowering season, he assessed the genetic composition of the seeds produced by *P. drummondii*. The data collected by Levin are shown in the work with the data exercise in Investigating Life: Flower Color Reinforces a Reproductive Barrier in Phlox. Consider, however, the following hypothetical results:

Morph (flower color)	Number of seeds (progeny)		
	<i>P. drummondii</i>	Hybrid	Total
Red	151 (87%)	23 (13%)	174
Pink	101 (67%)	49 (33%)	270

Calculate the 95% confidence intervals for the proportion of hybrid seeds in red- and pink-flowered *P. drummondii*. There are many websites available for calculating confidence intervals; a good one is the Vassar College statistical computation site, VassarStats.net. You can go to this site and select "Proportions" from the left-hand menu, then select "The Confidence Interval of a Proportion." What are the numerical values of the 95% confidence intervals?

Correct answer: For red flowers, the proportion of seeds from hybrid matings is 0.1322 (23/174). The 95% confidence limits of this proportion are approximately 0.09–0.19. For pink flowers, the proportion of seeds from hybrid matings is 0.3296 (49/270). The 95% confidence limits of this proportion are approximately 0.27–0.38.

in LaunchPad

“I especially like the **“Work with the Data”** exercises. Too often this sort of critical thinking is left to upper level courses.”

—Susan Reigler, Indiana University Southeast

Apply What You’ve Learned

Exploring the same types of problems that scientists typically investigate, the **Apply What You’ve Learned** exercises allow students to hone both critical thinking and data analysis skills in fascinating contexts. Answers appear in the back of the book.

How Does Statistics Help Us Understand the Natural World?

Statistics is essential to scientific discovery. Most biological studies involve five basic steps, each of which requires statistics:

- **Step 1: Choose an Experimental Design**
Clearly define the scientific question and the methods necessary to tackle the question.
- **Step 2: Collect Data**
Gather information about the natural world through observations and experiments.
- **Step 3: Organize and Visualize the Data**
Use tables, graphs, and other useful representations to gain intuition about the data.
- **Step 4: Summarize the Data**
Summarize the data with a few key statistical calculations.
- **Step 5: Make Inferences from the Data**
Use statistical methods to draw general conclusions from the data about the world and the ways it works.

Step 1: Choose an Experimental Design

We make observations and conduct experiments to gain knowledge about the world. Scientists come up with scientific ideas based on

Making Sense of Data: A Statistics Primer

This primer (an appendix in the text and also in LaunchPad), lays the proper groundwork for understanding statistics and data, providing helpful student support for all of the quantitative exercises in the new edition.

Life in LAUNCHPAD

LAUNCHPADWORKS.COM

Built to address the biggest classroom issues instructors face, LaunchPad gives students everything they need to prepare for class and exams, while giving instructors everything they need to quickly set up a course, shape the content to their syllabus, craft presentations and lectures, assign and assess homework, and guide the progress of individual students and the class as a whole.

All of the resources in LaunchPad for *Life*, Eleventh Edition have been created specifically to support this edition. The **Activities** and **Animations** were created using textbook art; all quiz and test questions are updated and aligned to the Eleventh Edition; everything is referenced to the textbook's Key Concepts; and substantial new active learning resources support the use of the book in an active learning context.

Searchable Question Bank

LaunchPad's enhanced question bank functionality makes it easier to search for and select questions from any of the *Life* question banks (Test Bank, Learning-Curve, Summative Quizzes). With the new filtering functionality, instructors can get the precise mix of questions they want by filtering for:

- Learning Outcome (new for the Eleventh Edition)
- Focus Your Learning statement
- Key Concept
- Bloom's Level

- Difficulty (for LearningCurve questions)
- Source

NEW RELEASE!

LearningCurve adaptive quizzing gives each student individualized question sets and feedback based on their correct and incorrect responses. All the questions link back to the eBook to encourage students to read the book in preparation for classtime and exams.

Updated Interface

LearningCurve's new streamlined user experience makes features such as the Study Plan, eBook, and Hints more prominent. Also new—all questions now feature text hints to guide the student's thinking.

Instructor Customization

LearningCurve organizes chapter quizzes by Key Concept and makes it easy for instructors to hide questions on concepts they are not covering. With this, each student's quizzes can focus on the exact content being taught.

The screenshot displays the LearningCurve interface. At the top, a red 'NEW' banner is visible. The main header reads 'Chapter 10 Photosynthesis: Energy from Sunlight'. Below this, a 'Target score progress' bar shows 'You have: 226 points' and 'Target: 750'. A button for 'LearningCurve tips for success' is present. The central area contains a quiz question: 'What can local changes in membrane potential generate?'. The question text is 'Why is it important for a neuron to maintain a membrane potential instead of allowing ions to reach equilibrium?'. Five multiple-choice options are listed, each with a radio button. At the bottom of the question area, there are buttons for 'Get a hint (fewer points)' and 'Show answer (no points)'. A sidebar on the right, titled 'Your personalized study plan', lists several key concepts with their respective accuracy percentages: 'Key Concept 10.1 Photosynthesis Uses Light to Make Carbohydrate' (48%), 'Key Concept 10.2 Photosynthesis Converts Light Energy into Chemical Energy' (78%), 'Key Concept 10.3 Chemical Energy Trapped in Photosynthesis Is Used to Synthesize Carbohydrates' (33%), 'Key Concept 10.4 Plants Have Adapted Photosynthesis to Environmental Conditions' (33%), and 'Key Concept 10.5 Photosynthesis is an Integral Part of Plant Metabolism' (100%). Below these, 'Study plan suggestions' include an eBook and an animated tutorial.

Life and ASSESSMENT

Life's assessment resources have long been appreciated for their accuracy, clarity, and ease-of-use. For this edition, we have enriched our assessment program to offer instructors more of exactly what they want. Along with updating and revising all assessment banks and adding new questions at higher cognitive levels, we have fully aligned all in-book and online content for the Eleventh Edition to the new Learning Outcomes.

Learning outcomes

The new **Learning Outcomes** in *Life* are the core of the book's learning standards (Key Concepts, Focus Your Learning statements, and Learning Outcomes). Each chapter in this edition is structured around these standards. In the book, Learning Outcomes are aligned to Focus Your Learning statements, which are in turn aligned with Key Concepts. Learning Outcomes appear in the Recaps, where they show students what they should be able to do after reading a Key Concept section. Questions in the Recaps allow students to test themselves on those Learning Outcomes (and answers are in the back of the book).

The *Life Test Bank* has been significantly revised for the Eleventh Edition, to meet four goals:

- Update content to match the revised textbook chapters
- Align questions to the new Learning Outcomes
- Increase the number of questions with higher cognitive (Bloom's) levels
- Develop a new section of short answer questions to allow for open-ended questions and problems that don't fit the multiple choice or fill-in-the-blank framework

All questions are available in LaunchPad and are easily searchable by Chapter, Key Concept, Focus Your Learning statement, Learning Outcome, and Bloom's level using LaunchPad's new question bank tools.

Assessment in the Book and in LaunchPad

FEATURE	LAUNCHPAD ASSESSMENT RESOURCES
Key Concepts	• All quiz and test questions are tagged by Key Concept and searchable in LaunchPad • LearningCurve study plans and instructor reports are organized around the Key Concepts
Focus Your Learning Statements	• Questions in Recaps for students • All quiz and test questions are tagged by Focus Your Learning statement and are searchable in LaunchPad
Learning Outcomes	All Recap, quiz, and test questions are aligned with Learning Outcomes and are searchable in LaunchPad
Work with the Data	Companion Work with the Data exercises in LaunchPad
Summative Quizzes	Each chapter includes a pre-built Summative Quiz in LaunchPad
Active Learning Modules	All new Active Learning Modules include a pre-quiz, and post-quiz in LaunchPad, plus additional assessment questions
Simulations	Companion quizzes assignable in LaunchPad
Animations	Pre-built quizzes in LaunchPad
Activities	All activities are now assignable and report on completion to the LaunchPad gradebook
Test Bank	An extensive test bank is provided for each chapter, in a variety of formats: LaunchPad question banks, Word documents, and in the Diploma test-

Life is VISUAL

The art in *Life*, Eleventh Edition surpasses the art in previous editions. The authors and artists have examined each and every figure in the text, refining them for clarity, readability, and beauty. Many figures now include a question.

“The figures [in [Chapter 53](#)] blew me away. **They are sophisticated, elegant, and packed with information** without being cluttered.”

—Jill DeVito, University of Texas, Arlington

Focus Figures

Throughout the new edition, students will find specially created figures that take them through an essential concept. These illustrations let students know that a particular concept is absolutely essential, needs their full attention, and gives them a more interactive experience with the material.

Each of these figures concludes with a **thought-provoking question** that can lead to further exploration as the student is working through the text—another way of encouraging students to be active learners. Answers are in the back of the book.

Life is **CURRENT**

Life, Eleventh Edition Content Updates

PART 1: The Science of Life and Its Chemical Basis

- › Streamlined and more focused description of electron orbitals
- › Additional examples of functional groups and roles in biological molecules
- › Additional examples of protein functions
- › Reorganization and clearer presentation of the levels of protein structure
- › Updated information on the search for evidence of conditions for life outside of Earth

PART 2: Cells

- › Discovery of a new organelle, the tannosome, that encloses pigments
- › New discussion of substructure and instability of microtubules
- › Reorganization of discussion of membrane structure to feature connections with the cytoskeleton inside the cell
- › Overview of membrane permeability of various substances
- › Further discussion of the roles of receptor agonists and antagonists in human behavior and metabolism
- › Clarification of the targets and roles of protein kinases

PART 3: Cells and Energy

- › Clarification of the chemistry and role of ATP in energy metabolism
- › New discussion of ribozymes along with protein enzymes
- › Description of the mechanism of aspirin as an example of enzyme inhibition
- › New description of feedback inhibition of the purine pathways and its role in arthritis
- › Clearer description of electron transport and ATP synthesis, and their role in fat metabolism
- › Clarification of the structure and function of photosynthetic reaction centers

PART 4: Genes and Heredity

- › Revised and clarified discussion of DNA packaging into chromosomes
- › More emphasis on human genetics (e.g., red hair)
- › More examples of problem solving in genetics to clarify concepts
- › Clarification of the aspects of DNA structure that allow specific interactions with other molecules
- › Clarification of the functions of telomeres and telomerases
- › Experimental and genetic evidence for the identification of a human disease-causing mutation and gene (e.g., breast cancer)
- › More emphasis on the new field of epigenetics (e.g., behavior)
- › Clearer description of the roles of small RNAs in gene regulation

PART 5: Genomes

- › Consolidated two chapters on development and evolution to a single chapter with focus on molecular and evolutionary aspects
- › Coverage of a new and powerful gene modification method: CRISPR
- › Emphasis on evolutionary aspects of genome sequencing (e.g., cats)

- › Updated information on the human genome sequence
- › Reorganization and update of discussion of synthetic biology
- › Updated discussion of stem cells and their applications, including veterinary and human medicine

PART 6: The Patterns and Processes of Evolution

- › New Investigating Life thread about the evolution of echolocation, and ways moths have evolved to avoid detection by echolocation
- › Updated information about the evolution of Darwin's finches, as an example of the relationship between speciation and geographic isolation
- › Added studies about the evolution of flu viruses, cross-species transfers, and why the 1918 flu epidemic was so severe
- › New experiments about the factors that influence the extinction of populations

PART 7: The Evolution of Diversity

- › Updated studies that clarify the evolution of eukaryotes within the archaeans
- › New experiments and information about the communication among bacteria through quorum sensing
- › Added experiments and applications about biofuel production from algae
- › New experiments and problems about the application of fungal diversity to study environmental change
- › Updated information about the phylogeny of animals, and what it tells us about the evolution of nervous systems
- › New information and experiments about the evolution of viviparity, and the advantages and disadvantages of viviparity versus oviparity

PART 8: Flowering Plants: Form and Function

- › Clear illustrated summary of anatomical differences between monocots and dicots
- › Experimental evidence for the role of plant vascular tissue in transporting substances in the stem (e.g., cyanogenic glycosides)
- › Greater emphasis on the role of mycorrhizae in plant nutrition
- › Discussion of the role of apomixis in plant reproduction and its potential applications
- › Update on plant diseases and resistance (e.g., wheat rust)

PART 9: Animals: Form and Function

- › Description of a previously unrecognized mammalian adaptation for heat loss and the development of a new technology that amplifies that adaptation to improve physical performance
- › Graphic description of the neuromuscular coupling extending to the control of Ca^{2+} release from the sarcoplasmic reticulum
- › Investigation of the use of RNAi to prevent hypertrophic cardiomyopathy
- › Fascinating investigations of the capacity of seals to spend most of their time underwater and not breathing
- › Exceedingly clear presentations of the mechanisms of membrane potentials, action potentials,

conduction of action potentials, and synaptic transmission

- Use of pit viper infrared sensory system to investigate transient receptor potential proteins
- Exciting story of being able to see what a rat thinks—at least in terms of the memory of place

PART 10: Ecology

- More attention is given to the importance of scale and multiple levels of organization in ecology. Special emphasis has been placed on global change and the role of humans as part of Earth's systems
- Inclusion of more quantitative and conceptual material with a focus on visualization (through figures) and active learning (through Work with the Data questions)
- Examples have been diversified; fewer insect examples and more marine, invasive species, and endangered species examples
- New content on the role of ecology in human society and how it differs from environmental science and environmentalism
- New content on the effects of Earth's topography on physical processes such as temperature inversion, ocean upwelling, and rain shadow effects
- Major revision and reorganization of population growth models and examples, including new material on life table analysis
- New content on disturbance and succession including the concept of alternative stable states
- New content on nutrient cycling at ecosystem and global scales, including decomposition, nutrient transformations, and the causes of climate change
- New content on the mechanisms behind species extinctions including the concept of extinction vortex
- New content on the causes and consequences of biodiversity loss including pollution, overharvesting, invasive species, emerging diseases, and the effects of climate change

Updates to the Media and Assessment Resources

Activities

- A new format for most activities, designed to better engage the student
- New functionality that reports to the LaunchPad gradebook upon activity completion

Simulations

- Twelve new simulations on topics such as Macromolecules, Active and Passive Transport, and Natural Selection
- Each simulation is now accompanied by an assignable quiz in LaunchPad

Animations

- A new video format that incorporates captions directly into the video

Work with the Data

- Each in-book Work with the Data exercise has an online companion exercise in LaunchPad, designed to give students practice with the same analytical skills

Active Learning Exercises

- Extensively revised and reformatted

New Active Learning Guide

- A thorough primer on active learning in biology
- Includes sections such as:
 - What is active learning?
 - Designing your course for active learning
 - Using active learning in the classroom
 - How to implement *Life* 11e resources
- Chapter-by-chapter ideas, suggestions, and resources

New Active Learning Modules

- Robust modules designed to provide all the support an instructor needs to teach selected topics in an active learning setting
- Each module includes a detailed instructor's guide, a pre-quiz, a pre-class video, an in-class exercise, a post-quiz, and assessment questions

Test Bank

- All questions aligned to new Learning Outcomes
- A new set of short answer questions in each chapter
- Additional questions at higher Bloom's Levels

LearningCurve

- Expanded question banks for each chapter
- New fill-in-the-blank questions
- Hints added to all questions

Acclaim for Life

"This textbook **fits nicely with the current focus** on active learning and the AAAS Vision and Change report."

—Michael Baltzley, Western Oregon University

"In most cases, I found the text to be exceptionally well-written and clear... The author(s) were **particularly good at explaining 'big' concepts...** The writing/presentation style of the author(s) was very readable.... In particular, the author(s) use a number of **'real-world' examples** to highlight the information in the text. I found that this made the text and information very relatable and easier to follow/understand."

—Mike Shaughnessy, Northeastern State University

“The authors and publishing team are to be commended for producing a set of products that promise to promote active learning. The products of Life 11e contain **numerous, novel features that distinguish them from similar products.**”

—David Marcey, California Lutheran University

“Opening with an intriguing story with promise of future investigation is the way to go. Many freshmen, introductory biology courses have a large number of students interested in medicine/medical fields. When “real” scenarios can be used to supplement the material within the chapter and help a student make those applicable connections, **the chapter is much more interesting and meaningful.**”

—Melissa Reedy, University of Illinois, Urbana-Champaign

“Without question, **my favorite element was the open-ended concept questions included in the section recaps.** These questions are well-written, thought provoking, not easily answered or looked up, and require an understanding of the concepts rather than a memorization of flash card terms.”

—Brad Mehrtens, University of Illinois, Urbana-Champaign

“I love that [Connect the Concepts] makes a direct connection to earlier text/figures; this **emphasizes and encourages the integrative**, rather than linear, **process of learning biology.**”

—Tess Killpack, Wellesley College

“I really like the **extensive use of examples and the figures**, recaps, problems, etc. I think this makes the chapter much more accessible to students and gives them a built-in way to test their understanding beyond simple memorization questions. These features are what make this chapter and the other ecology chapters in this text that I have reviewed stand out from other texts.”

—Amy Downing, Ohio Wesleyan University

“I did find the chapter engaging specifically because **real case studies were used** as part of the conceptual framework. This was one of the major points that biology educators were calling for at the Vision and Change forum a few years ago.”

—Andrew David, Clarkson University

Authors

DAVID HILLIS

SALLY HACKER

CRAIG HELLER

DAVID SADAVA

DAVID SADAVA is the Pritzker Family Foundation Professor of Biology, Emeritus at the Keck Science Center of Claremont McKenna, Pitzer, and Scripps, three of The Claremont Colleges. In addition, he is Adjunct Professor of Cancer Cell Biology at the City of Hope Medical Center in Duarte, California. Twice winner of the Huntoon Award for superior teaching, Dr. Sadava has taught courses on introductory biology, biotechnology, biochemistry, cell biology, molecular biology, plant biology, and cancer biology. In addition to *Life: The Science of Biology* and *Principles of Life*, he is the author or coauthor of books on cell biology and on plants, genes, and crop biotechnology. His research has resulted in many papers coauthored with his students, on topics ranging from plant biochemistry to pharmacology of narcotic analgesics to human genetic diseases. For the past 20 years, he has investigated multidrug resistance in human small-cell lung cancer with a view to understanding and overcoming this clinical challenge. At the City of Hope, his current work focuses on new anti-cancer agents from plants. He is the featured lecturer in “Understanding Genetics: DNA, Genes and their Real-World Applications” and “What Science Knows About Cancer” video courses for The Great Courses series.

DAVID M. HILLIS is the Alfred W. Roark Centennial Professor in Integrative Biology and the Director of the Dean’s Scholars Program at the University of Texas at Austin, where he also has directed the School of Biological Sciences and the Center for Computational Biology and Bioinformatics. Dr. Hillis has taught courses in introductory biology, genetics, evolution, systematics, and biodiversity. He has been elected to the National Academy of Sciences and the American Academy of Arts and Sciences, awarded a John D. and Catherine T. MacArthur fellowship, and has served as President of the Society for the Study of Evolution and of the Society of Systematic Biologists. He served on the National Research Council committee that wrote the report *BIO 2010: Transforming Undergraduate Biology Education for Research Biologists*, and he serves on the Executive Committee of the National Academies Scientific Teaching Alliance. His research interests span much of evolutionary biology, including experimental studies of viral evolution, empirical studies of natural molecular evolution, applications of phylogenetics, analyses of biodiversity, and evolutionary modeling. He is

particularly interested in teaching and research about the practical applications of evolutionary biology.

H. CRAIG HELLER is the Lorry I. Lokey/Business Wire Professor in Biological Sciences and Human Biology at Stanford University. He has taught neurobiology and physiology in the core biology courses at Stanford since 1972 and served as Director of the Program in Human Biology, Chairman of the Biology Department, and Associate Dean of Research. Dr. Heller is a fellow of the American Association for the Advancement of Science and a recipient of the Walter J. Gores Award for excellence in teaching and the Kenneth Cuthbertson Award for Exceptional Service to Stanford University. His research is on the neurobiology of sleep and circadian rhythms, mammalian hibernation, the regulation of body temperature, the physiology of human performance, and the neurobiology of learning and memory. He has done research on many species and problems ranging from sleeping kangaroo rats, diving seals, hibernating bears and squirrels, photoperiodic hamsters, and exercising athletes. Dr. Heller has extended his enthusiasm for promoting active learning via the development of a two-year curriculum in human biology for the middle grades and through the production of Virtual Labs—interactive computer-based modules to teach physiology.

SALLY D. HACKER is Professor at Oregon State University where she has been a faculty member since 2004. She has taught courses in introductory ecology, community ecology, invasion biology, field ecology, and marine biology. She was awarded the Murray F. Buell Award by the Ecological Society of America and the Young Investigator Prize by the American Society of Naturalists. Dr. Hacker's research explores the structure, function, and services of natural and managed ecosystems under varying contexts of species interactions and global change. She has conducted research with plants and animals in rocky intertidal, salt marsh, seagrass, and coastal dune ecosystems. Her work has most recently focused on the protective role of dune ecosystems in mitigating coastal vulnerability due to climate change. In addition to the textbooks *Life: The Science of Biology* and *Ecology* (Sinauer Associates), she is author or coauthor on numerous articles and book chapters exploring community ecology, species interactions, marine invasions, and ecosystem services important to coastal management. She is particularly interested in promoting active and experiential learning for students interested in ecology and field-emersion experiences.

Acknowledgments

While our names are on the cover and we take ultimate responsibility for the contents of this book, we relied on many people for help. On the editorial side, first and foremost was the Advisory Board, whose names follow these paragraphs. These biologists, from institutions large and small that are research- and teaching-oriented, were with us every step of the way. At the outset, as we planned the very different approaches that you can see in this edition, they provided invaluable critiques to our proposals, with many of the advisors having experiences in active teaching environments that are different from ours. Then as we wrote the chapters and designed the illustrations that shaped the reality of our proposals, the Board again provided very useful evaluations. Finally, with their varied experiences in using online material, the members of the Advisory Board were an important source of feedback as we developed the active learning and assessment materials associated with the book. We couldn't have done it as well without them.

On the following pages, you can see three lists of chapter reviewers totaling more than 400 individuals. First were between edition reviewers, who carefully looked at the previous edition of *Life* and told us what we could do better, leave out, or add in the new edition. Then, accuracy reviewers, many of them experts in their field, examined each of our chapters for accuracy and not only spotted errors of fact and concepts, but made suggestions for better presentation. Finally, with our emphasis on active learning and pedagogy, we asked a group of experienced experts in biology education to critique our pedagogical features and give us suggestions for improvement. We are grateful to each and every one of these reviewers.

The team we worked intimately with at Sinauer Associates over many months consisted of a number of old friends and some new ones. In the former category are David McIntyre, who still manages to find fresh and exquisite photographs that illuminate our concepts; Jason Dirks, who directs a team of talented media and supplements editors and writers; Johannah Walkowicz, who again recruited the multitude of reviewers listed here; Joan Gemme, who designed the cover and skillfully arranged the words and images on every page, and, along with Joanne Delphia, designed the interior to provide a fresh look; Chris Small, whose behind the scenes skill at coordinating all facets of art and production remain invaluable; Dean Scudder, who continues to bring a wealth of insight to how best to tell our story; Azelie Fortier, whose interactions with the Advisory Board and potential adopters have informed the development of our new active learning features; and Liz Pierson, the most insightful copyeditor we know.

New to the *Life* team were the editors at Sinauer Associates, Danna Lockwood and Chelsea Holabird, who worked creatively (and tirelessly) to assure that each of our chapters lived up to the challenging goals we set for this Eleventh Edition. Carol Pritchard-Martinez came back after a hiatus to provide superb guidance as our developmental editor. Also, Carrie Mailler provided critical knowledge about our foray into the world of pedagogy and learning objectives.

Macmillan Learning has worked aggressively to bring *Life* to a broader audience. Executive Marketing Manager Will Moore, Executive Editor Andy Dunaway, and Editor Beth Cole (who was our liaison in the early stages of this edition), along with the regional specialists, regional managers, and experienced sales force, are effective ambassadors and skillful transmitters of the strong new features and unique strengths of this new edition. We depend upon their experience and energy to keep us in touch with how *Life* is perceived by its users. Many thanks also to Chris Efstratiou and the whole Macmillan LaunchPad production team.

Finally and above all, we thank Andy Sinauer. Andy is the ideal publisher for his authors. He loves biology, is committed to education, and sets high standards. Throughout the preparation of this new edition, he has been not just our editor but also our guiding spirit.

Media and Supplements

to accompany *Life: The Science of Biology*, Eleventh Edition

LaunchPad is the easy-to-use online platform that integrates the e-Book, all of the student and instructor media resources, and assessment functions into one clean, unified interface. For more about LaunchPad, see [pages xvi-xix](#) and visit macmillanlearning.com/LaunchPad.

Student Resources

ACTIVITIES. A range of interactive activities helps students learn and review key facts and concepts through labeling diagrams, identifying steps in processes, and working with simulations of biological systems and processes.

ANIMATIONS. In-depth animations present complex topics in a clear, easy-to-follow format. Each is accompanied by a brief quiz.

MEDIA CLIPS. These engaging video clips depict fascinating examples of some of the many organisms, processes, and phenomena discussed in the textbook.

BIONEWS FROM SCIENTIFIC AMERICAN. BioNews makes it easy for instructors to bring the dynamic nature of the biological sciences and up-to-the-minute currency into their course via an automatically updated news feed in LaunchPad.

WORK WITH THE DATA. Online companions to the Work with the Data exercises in the textbook.

FLASHCARDS. A convenient way for students to learn and review the extensive terminology of introductory biology.

TREE OF LIFE. An interactive version of the Tree of Life from [Appendix A](#), with links to a wealth of information on each group listed.

MATH FOR LIFE. A collection of mathematical shortcuts and references to help students with the quantitative skills they need in the biology laboratory.

SUMMATIVE QUIZZES. Pre-built quizzes that assess overall student understanding of each chapter.

LEARNINGCURVE. A powerful adaptive quizzing system with a game-like format that engages students. See [pages xvii-xviii](#) for details.

Instructor Resources

TEXTBOOK FIGURES AND TABLES. Every figure and table from the textbook (including all photos and all unnumbered figures) is provided in both JPEG and PowerPoint formats, in multiple versions, including whole, reformatted, and unlabeled.

POWERPOINT RESOURCES. For each chapter of the textbook, several different PowerPoint presentations are available, providing instructors the flexibility to build presentations in the

manner that best suits their needs:

- › Textbook Figures and Tables
- › Lecture Presentations
- › Layered Art Figures
- › Active Learning Exercises (see below)
- › Active Learning Modules (see below)

VIDEOS. Featuring many new videos for the Eleventh Edition, the wideranging collection of video segments helps demonstrate the complexity and beauty of life.

ACTIVE LEARNING GUIDE. New for the Eleventh Edition, this guide provides an excellent overview of active learning techniques in biology, along with chapter-specific support. See page xiii for details.

ACTIVE LEARNING EXERCISES. Set up for easy integration into lectures, these short exercises pose questions or problems for the class to discuss or solve. Each also includes a multiple-choice element, for easy use with clicker systems.

ACTIVE LEARNING MODULES. New for the Eleventh Edition, these comprehensive modules provide instructors everything they need to teach selected key topics using an active learning approach. See page xii for details.

INSTRUCTOR'S MANUAL. The Instructor's Manual includes the following sections for each chapter: *Overview*, *What's New*, *Chapter Opener Resources* (Discussion Questions and Online Resources), *Chapter Outline*, and *Key Terms*.

LEARNING OUTCOMES. The new Learning Outcomes provide instructors using *Life*, Eleventh Edition a thorough set of learning standards, to which all of the assessment resources are aligned. See [pages x](#) and [xviii](#) for details.

TEST BANK. The *Life* Test Bank includes over 7,000 questions, all referenced to specific Key Concepts, Learning Outcomes, and Bloom's Levels. Each chapter includes a wide range of multiple-choice, fill-in-the-blank, and short-answer questions.

COMPUTERIZED TEST BANK. (CD, ISBN 978-1-319-08581-0) The entire Test Bank, plus the Summative Quizzes and LearningCurve questions are all included in Blackboard's easy-to-use Diploma program (software included). Designed for both novices and advanced users, Diploma allows instructors to quickly and easily create or edit questions and create quizzes or exams.

COURSE MANAGEMENT SYSTEM SUPPORT. As a service for *Life* adopters using Blackboard, Moodle, Desire2Learn, or other course management systems, full electronic course packs are available.

Additional Resources

Increase participation. Confirm understanding. Measure performance.

iclicker is an award-winning student response solution that allows you to easily transform your classroom into an active learning environment. For more information, visit iclicker.com.

Macmillan Learning Lab Solutions

Macmillan Learning Lab Solutions unites the same brands you know and trust—W. H. Freeman, Hayden-McNeil, Sapling Learning, and Late Nite Labs—and provides the resources to build a seamless, comprehensive lab experience for your students. For more information, visit macmillanlearning.com/LabSolutions.

CatchUp Math & Stats for the Life Sciences

Michael Harris, Gordon Taylor, and Jacquelyn Taylor

(ISBN 978-1-4292-0557-3)

Presented in brief, accessible units, this primer will help students quickly brush up on the quantitative skills they need to succeed in biology.

A Student Handbook for Writing in Biology, Fifth Edition

Karin Knisely (ISBN 978-1-3191-2181-5)

This book provides practical advice to students who are learning to write according to the conventions in biology, using the standards of journal publication as a model.

BioStats Basics: A Student Handbook

James L. Gould and Grant F. Gould (ISBN 978-0-7167-3416-1)

Engaging and informal, *BioStats Basics* provides introductory-level biology students with a practical, accessible introduction to statistical methodology.

Inquiry Biology: A Laboratory Manual, Volumes 1 and 2

Mary Tyler, Ryan W. Cowan, and Jennifer L. Lockhart (Volume 1 ISBN 978-1-4292-9288-7; Volume 2 ISBN 978-1-4292-9289-4)

This introductory biology laboratory manual is inquiry-based—instructing in the process of science by allowing students to ask their own questions, gather background information, formulate hypotheses, design and carry out experiments, collect and analyze data, and formulate conclusions.

Hayden-McNeil Life Sciences Lab Notebook

(ISBN 978-1-4292-3055-1)

This durable, high-quality carbonless laboratory notebook allows students to hand in originals or copies of their lab work, not entire composition books. The Lab Notebook contains Hayden-McNeil's unique white paper carbonless copies and biology-specific reference materials.

The Scientific Teaching Book Series

The Series is a collection of practical guides, intended for all science, technology, engineering and mathematics (STEM) faculty who teach undergraduate and graduate students in these disciplines. The purpose of these books is to help faculty become more successful in all aspects of teaching and learning science, including classroom instruction, mentoring students, and professional development. Authored by well-known science educators, the Series provides concise descriptions of best practices and how to implement them in the classroom, the laboratory, or the department. For readers interested in the research results on which these best practices are based, the books also provide a gateway to the key educational literature. The Series includes:

Scientific Teaching

Jo Handelsman, Sarah Miller, and Christine Pfund

(ISBN 978-1-4292-0188-9)

Transformations: Approaches to College Science Teaching

Deborah Allen and Kimberly Tanner (ISBN 978-1-4292-5335-2)

Entering Research: A Facilitator's Manual

Janet L. Branchaw, Christine Pfund, and Raelyn Rediske

(ISBN 978-1-4292-5857-9)

Discipline-Based Science Education Research: A Scientist's Guide

Stephanie J. Slater, Timothy F. Slater, and Janelle M. Bailey

(ISBN 978-1-4292-6586-7)

Assessment in the College Classroom

Clarissa Dirks, Mary Pat Wenderoth, and Michelle Withers

(ISBN 978-1-4292-8197-3)

Contents

PART ONE The Science of Life and Its Chemical Basis

1 Studying Life

Investigatinglife Corals in Hot Water

Living Organisms Share Similarities and a Common Origin

Life arose from non-life via chemical evolution

Cellular structure evolved in the common ancestor of life

Photosynthesis allows some organisms to capture energy from the sun

Biological information is stored in a genetic code common to all organisms

Populations of all living organisms evolve

Biologists trace the evolutionary tree of life

Cellular differentiation and specialization underlie multicellular life

Organisms extract energy and raw materials from the environment

Living organisms must regulate their internal environment

Living organisms interact

Biologists Investigate Life through Experiments That Test Hypotheses

Observing and quantifying are important skills

Scientific methods combine observation, experimentation, and logic

Good experiments have the potential to falsify hypotheses

Statistical methods are essential scientific tools

Investigatinglife Corals in Hot Water

Experiment

Work with the data

Discoveries in biology can be generalized

Not all forms of inquiry are scientific

Understanding Biology Is Important for Health, Well-Being, and Public-Policy Decisions

Modern agriculture depends on biology

Biology is the basis of medical practice

Biology can inform public policy

Biology is crucial for understanding ecosystems

Biodiversity helps us understand, enjoy, and appreciate our world

Apply What You've Learned

2 Small Molecules and the Chemistry of Life

Investigatinglife Tracking a Dinosaur

Atomic Structure Explains the Properties of Matter

What are atoms?

An element consists of only one kind of atom

Each element has a unique number of protons

The number of neutrons differs among isotopes

Investigatinglife Determining Beef Source in Big Macs Using Isotope Analysis

Experiment

Work with the data

The behavior of electrons determines chemical bonding and geometry

Atoms Bond to Form Molecules

Covalent bonds consist of shared pairs of electrons

Ionic attractions form by electrical attraction

Hydrogen bonds may form within or between molecules with polar covalent bonds

Hydrophobic interactions bring together nonpolar molecules

van der Waals forces involve contacts between atoms

Atoms Change Partners in Chemical Reactions

Water Is Critical for Life

Water has a unique structure and special properties

The reactions of life take place in aqueous solutions

Aqueous solutions may be acidic or basic

Apply What You've Learned

3 Proteins, Carbohydrates, and Lipids

Investigatinglife Weaving a Web

Macromolecules Characterize Living Things

Chemical groupings determine the structures of macromolecules

The structures of macromolecules reflect their functions

Investigatinglife Making Spider Silk

Experiment

Work with the data

Most macromolecules are formed by condensation and broken down by hydrolysis

The Function of a Protein Depends on Its Three-Dimensional Structure

Monomers of proteins link together to make the macromolecule

Peptide linkages form the backbone of a protein

The primary structure of a protein is its amino acid sequence

The secondary structure of a protein requires hydrogen bonding

The tertiary structure of a protein is formed by bending and folding

The quaternary structure of a protein consists of subunits

Shape and surface chemistry contribute to protein function

Environmental conditions affect protein structure

Experiment Primary Structure Specifies Tertiary Structure

Work with the data Primary Structure Specifies Tertiary Structure

Protein shapes can change

Molecular chaperones help shape proteins

Simple Sugars Are the Basic Structural Unit of Carbohydrates

Monosaccharides are simple sugars

Glycosidic linkages bond monosaccharides

Polysaccharides store energy and provide structural materials

Chemically modified carbohydrates contain additional functional groups

Lipids Are Defined by Their Solubility Rather Than by Chemical Structure

Fats and oils are triglycerides

Phospholipids form biological membranes

Some lipids have roles in energy conversion, regulation, and protection

Apply What You've Learned

4

Nucleic Acids and the Origin of Life

Investigatinglife Looking for Life

Nucleic Acid Structures Reflect Their Functions

Nucleic acids are informational macromolecules

Base pairing occurs in both DNA and RNA

DNA carries information and is expressed through RNA

The DNA base sequence reveals evolutionary relationships

Nucleotides have other important roles

The Small Molecules of Life Originated on Primitive Earth

Living organisms do not repeatedly come from inanimate nature

Experiment Disproving the Spontaneous Generation of Life

Life began in water

Prebiotic synthesis experiments model early Earth

Experiment Could Biological Molecules Have Been Formed from Chemicals Present in Earth's Early Atmosphere?

Life may have come from outside Earth

Investigatinglife Can We Find Evidence of Life on Mars?

Experiment

Work with the data

The Large Molecules of Life Originated from Small Molecules

Complex molecules could be formed from simpler ones on primitive Earth

RNA may have been the first biological catalyst

Cells Originated from Their Molecular Building Blocks

How did the first cells with membranes come into existence?

Some ancient cells left a fossil imprint

Apply What You've Learned

PART TWO Cells

5 Cells: The Working Units of Life

Investigatinglife Natural Sunscreen

Cells Are the Fundamental Units of Life

What is the cell theory?

Cell size is limited by the surface area-to-volume ratio

Microscopes reveal the features of cells

The cell membrane forms an outer boundary of every cell

Research tools Looking at Cells

Cells may be classified as either prokaryotic or eukaryotic

Prokaryotic Cells Are the Simplest Cells

What are the features of prokaryotic cells?

Specialized features are found in some prokaryotes

Eukaryotic Cells Contain Organelles

Compartmentalization is important to eukaryotic cell function
Organelles can be studied by microscopy or isolated for chemical analysis
Ribosomes are factories for protein synthesis
The nucleus contains most of the genetic information
Key tools Cell Fractionation
The endomembrane system is a group of interrelated organelles
Some organelles transform energy
There are several other membrane-enclosed organelles
The cytoskeleton is important in cell structure and movement

Discovering a New Organelle, the Tannosome

Experiment

Work with the data

Biologists can manipulate living systems to establish cause and effect
Experiment The Role of Microfilaments in Cell Movement—Showing Cause and Effect in Biology
Work with the data The Role of Microfilaments in Cell Movement—Showing Cause and Effect in Biology

Extracellular Structures Have Important Roles

What is the plant cell wall?

The extracellular matrix supports tissue functions in animals

Eukaryotic Cells Evolved in Several Steps

Internal membranes and the nuclear envelope probably came from the cell membrane
Some organelles arose by endosymbiosis

Apply What You've Learned

Cell Membranes

Sweating and Membranes

Biological Membranes Are Lipid–Protein Bilayers

Lipids form the hydrophobic core of the membrane
Membrane proteins are asymmetrically distributed
Key tools Membrane Proteins Revealed by the Freeze-Fracture Technique
Experiment Rapid Diffusion of Membrane Proteins
Membranes are constantly changing
Cell membrane carbohydrates are recognition sites

The Cell Membrane Is Important in Cell Adhesion and Recognition

Cell recognition and adhesion involve proteins and carbohydrates at the cell surface

Three types of cell junctions connect adjacent cells

Cell membranes adhere to the extracellular matrix

Substances Can Cross Membranes by Passive Processes

Diffusion is the process of random movement toward a state of equilibrium

Simple diffusion takes place through the phospholipid bilayer

Osmosis is the diffusion of water across membranes

Diffusion may be aided by channel proteins

Carrier proteins aid diffusion by binding substances

Aquaporins Increase Membrane Permeability to Water

Experiment

Work with the data

Active Transport across Membranes Requires Energy

Active transport is directional

Different energy sources distinguish different active transport systems

Large Molecules Enter and Leave a Cell through Vesicles

Macromolecules and particles enter the cell by endocytosis

Receptor-mediated endocytosis is highly specific

Exocytosis moves materials out of the cell

Apply What You've Learned

Cell Communication and Multicellularity

A Signal for Bonding

Signals and Signaling Affect Cell Function

Cells receive several types of signals

A signal transduction pathway involves a signal, a receptor, and responses: Overview

Receptors Bind Signals to Initiate a Cellular Response

Receptors that recognize chemical signals have specific binding sites

Receptors can be classified by location and function

Intracellular receptors are located in the cytoplasm or the nucleus

The Response to a Signal Spreads through the Cell

The cell amplifies its response to ligand binding

Second messengers can amplify signals between receptors and target molecules

Signal transduction is highly regulated

Cells Change in Response to Signals in Several Ways

Ion channels respond to signals by opening or closing

Enzyme activities change in response to signals

Investigatinglife

Is Oxytocin a “Trust” Signal in Humans?

Experiment

Work with the data

Signals can initiate DNA transcription

Adjacent Cells in a Multicellular Organism Can Communicate Directly

How do animal cells directly communicate?

Plant cells communicate through plasmodesmata

Modern organisms provide clues about the evolution of cell–cell interactions and multicellularity

Apply What You’ve Learned

PART THREE Cells and Energy

8

Energy, Enzymes, and Metabolism

Investigatinglife

How Aspirin Works

Physical Principles Underlie Biological Energy Transformations

There are two basic types of energy

There are two basic types of metabolism

The first law of thermodynamics: Energy is neither created nor destroyed

The second law of thermodynamics: Disorder tends to increase

Chemical reactions release or consume energy

Chemical equilibrium and free energy are related

ATP Plays a Key Role in Biochemical Energetics

ATP hydrolysis releases energy

ATP couples exergonic and endergonic reactions

Enzymes Speed Up Biochemical Transformations

To speed up a reaction, an energy barrier must be overcome

Enzymes bind specific reactants at their active sites

Enzymes lower the energy barrier but do not affect equilibrium

Enzymes Bring Substrates Together so Reactions Readily Occur

Enzymes can orient substrates

Enzymes can induce strain in the substrate

Enzymes can temporarily add chemical groups to substrates

Molecular structure determines enzyme function

Not all enzymes are proteins

Some enzymes require other molecules in order to function

The substrate concentration affects the reaction rate

Enzyme Activities Can Be Regulated

Enzymes can be regulated by inhibitors

How Do Anti-Inflammatory Drugs Work as Enzyme Inhibitors?

Experiment

Work with the data

Allosteric enzymes are controlled via changes in shape

Allosteric effects regulate many metabolic pathways

Many enzymes are regulated through reversible phosphorylation

Enzymes are affected by their environment

Apply What You've Learned

Pathways That Harvest Chemical Energy

A Weighty Matter

Cells Harvest Chemical Energy from Glucose Oxidation

How do cells obtain energy from glucose?

Redox reactions transfer electrons and energy

The coenzyme NAD^+ is a key electron carrier in redox reactions

An overview: Harvesting energy from glucose

In the Presence of Oxygen, Glucose Is Fully Oxidized

In the glycolysis pathway, glucose is partially oxidized

Pyruvate oxidation links glycolysis and the citric acid cycle

The citric acid cycle completes the oxidation of glucose to CO_2

Pyruvate oxidation and the citric acid cycle are regulated by the concentrations of starting materials

Oxidative Phosphorylation Forms ATP

What are the steps in oxidative phosphorylation?

The respiratory chain transfers electrons and protons, and releases energy

ATP is made through chemiosmosis

Experiments demonstrate chemiosmosis

Experiment An Experiment Demonstrates the Chemiosmotic Mechanism

Experiment

Work with the data

Some microorganisms use non-O₂ electron acceptors

In the Absence of Oxygen, Some Energy Is Harvested from Glucose

Cellular respiration yields much more energy than fermentation

The yield of ATP is reduced by the impermeability of mitochondria to NADH

Metabolic Pathways Are Interrelated and Regulated

Catabolism and anabolism are linked

Catabolism and anabolism are integrated

Metabolic pathways are regulated systems

Apply What You've Learned

10 Photosynthesis: Energy from Sunlight

Photosynthesis Uses Light to Make Carbohydrates

Photosynthesis involves light and gas exchange

Experiments with isotopes show that O₂ comes from H₂O in oxygenic photosynthesis

Atmosphere Affect It?

Experiment

Work with the data

Photosynthesis involves two pathways

2 Photosynthesis Converts Light Energy into Chemical Energy

Light energy is absorbed by pigments in photosynthesis

Light absorption results in photochemical change

Reduction leads to ATP and NADPH formation

Chemiosmosis is the source of the ATP produced in photophosphorylation

3 Chemical Energy Trapped in Photosynthesis Is Used to Synthesize Carbohydrates

How were the steps in carbohydrate synthesis elucidated?

Experiment Tracing the Pathway of CO₂

Work with the data Tracing the Pathway of CO₂

The Calvin cycle is made up of three processes

Light stimulates the Calvin cycle

4 Plants Have Adapted Photosynthesis to Environmental Conditions

How do some plants overcome the limitations of CO₂ fixation?

C₃ plants undergo photorespiration but C₄ plants do not

CAM plants also use PEP carboxylase

5 Photosynthesis Is an Integral Part of Plant Metabolism

Photosynthesis interacts with other metabolic pathways

Apply What You've Learned

PART FOUR Genes and Heredity

1 The Cell Cycle and Cell Division

Investigatinglife Immortal Cells

All Cells Derive from Other Cells

Prokaryotes divide by binary fission

Eukaryotic cells divide by mitosis followed by cytokinesis

The Eukaryotic Cell Division Cycle Is Regulated

Specific internal signals trigger events in the cell cycle

Investigatinglife What Controls the Reproduction of Cancer Cells?

Experiment

Work with the data

Growth factors can stimulate cells to divide

3 Eukaryotic Cells Divide by Mitosis

The centrosomes determine the plane of cell division

The spindle begins to form during prophase

Chromosome separation and movement are highly organized

Cytokinesis divides the cytoplasm

4 Cell Division Plays Important Roles in the Sexual Life Cycle

Sexual life cycles produce haploid and diploid cells

5 Meiosis Leads to the Formation of Gametes

Meiosis reduces the chromosome number

Chromatid exchanges during meiosis I generate genetic diversity

During meiosis homologous chromosomes separate by independent assortment

Meiotic errors lead to abnormal chromosome structures and numbers

The number, shapes, and sizes of the metaphase chromosomes constitute the karyotype

Polyploids have more than two complete sets of chromosomes

5 Cell Death Is Important in Living Organisms

Programmed cell death removes cells that do not benefit the organism

7 Unregulated Cell Division Can Lead to Cancer

Cancer cells differ from normal cells in important ways

Cancer cells lose control over the cell cycle and apoptosis

Experiment Does It Take Multiple Events to Trigger the Cancer Cell Cycle?

Cancer treatments target the cell cycle

Apply What You've Learned

2

Inheritance, Genes, and Chromosomes

Investigatinglife What Are the Rules of Inheritance?

Inheritance of Genes Follows Mendelian Laws

Mendel's laws arose from controlled crosses of pea plants

Mendel's first experiments involved monohybrid crosses

Investigatinglife Mendel's Monohybrid Experiments

Experiment

Work with the data

Mendel's first law states that the two copies of a gene segregate

Mendel verified his hypotheses by performing test crosses

Experiment Homozygous or Heterozygous?

Mendel's second law states that copies of different genes assort independently

Probability can be used to predict inheritance

Mendel's laws can be observed in human pedigrees

2 Alleles Can Produce Multiple Phenotypes

New alleles arise by mutation

Many genes have multiple alleles

Dominance is not always complete

In codominance, both alleles at a locus are expressed

Some alleles have multiple phenotypic effects

3 Genes Can Interact to Produce a Phenotype

Hybrid vigor results from new gene combinations and interactions

The environment affects gene action

Most complex phenotypes are determined by multiple genes and the environment

4 Genes Are Carried on Chromosomes

Linked genes are inherited together

Genes can be exchanged between chromatids and mapped

Experiment Some Alleles Do Not Assort Independently

Interpret with the data Some Alleles Do Not Assort Independently

Linkage is revealed by studies of the sex chromosomes

5 Some Eukaryotic Genes Are Outside the Nucleus

5 Prokaryotes Can Transmit Genes by Mating

Bacteria exchange genes by conjugation

Bacterial conjugation is controlled by plasmids

Apply What You've Learned

DNA and Its Role in Heredity

Targeting DNA Replication in Cancer Therapy

Experiments Revealed the Function of DNA as Genetic Material

Circumstantial evidence indicates that the genetic material is DNA

DNA from one type of bacterium genetically transforms another type

Experiment Genetic Transformation

Experiment Genetic Transformation by DNA

Phage infection experiments confirmed that DNA is the genetic material

Eukaryotic cells can also be genetically transformed by DNA

Experiment The Hershey–Chase Experiment

DNA Has a Structure That Suits Its Function

How did Watson and Crick deduce the structure of DNA?

Four key features define DNA structure

The double-helical structure of DNA is essential to its function

DNA Is Replicated Semiconservatively

An elegant experiment demonstrated that DNA replication is semiconservative

There are two steps in DNA replication

DNA polymerases add nucleotides to the growing chain

The Meselson–Stahl Experiment

Experiment

Interpret with the data

Many other proteins assist with DNA polymerization

The two DNA strands grow differently at the replication fork

Telomeres are not fully replicated and are prone to repair

4 Errors in DNA Can Be Repaired

Repair mechanisms preserve DNA

5 The Polymerase Chain Reaction Amplifies DNA

The polymerase chain reaction can make multiple copies of a DNA sequence

Apply What You've Learned

From DNA to Protein: Gene Expression

Employing the Genetic Code to Combat Superbugs

Genes Code for Proteins

Observations in humans led to the proposal that genes determine enzymes

Experiments on bread mold established that genes determine enzymes

Experiment One Gene, One Enzyme

With the data One Gene, One Enzyme

One gene determines one polypeptide

Information Flows from Genes to Proteins

Three types of RNA have roles in the information flow from DNA to protein

In some cases, RNA determines the sequence of DNA

DNA Is Transcribed to Produce RNA

RNA polymerases share common features

Transcription occurs in three steps

The genetic code specifies which amino acids will be included in the polypeptide

Deciphering the Genetic Code

Experiment

With the data

Eukaryotic Pre-mRNA Transcripts Are Processed prior to Translation

Noncoding sequences called introns often appear between genes in eukaryotic chromosomes

Pre-mRNA processing prepares the mRNA transcript for translation

The Information in mRNA Is Translated into Proteins

A transfer RNA carries a specific amino acid and binds to a specific mRNA codon

Each tRNA is specifically attached to an amino acid

The ribosome is the workbench for translation

Translation takes place in three steps

Polysome formation increases the rate of protein synthesis

Polypeptides Can Be Modified and Transported during or after Translation

How are proteins directed to their cellular destinations?

Mitochondria and chloroplasts make some of their own proteins and import others

Many proteins are modified after translation

Experiment Testing the Signal

Apply What You've Learned

15

Gene Mutation and Molecular Medicine

Investigatinglife The Angelina Jolie Effect

Mutations Are Heritable Changes in DNA

Mutations have different phenotypic effects

Point mutations are changes in single nucleotides

Chromosomal mutations are extensive changes in the genetic material

Retroviruses and transposons can cause loss-of-function mutations or duplications

Mutations can be spontaneous or induced

Mutagens can be natural or artificial

Some base pairs are more vulnerable than others to mutation

Mutations have both benefits and costs

Mutations in Humans Can Lead to Diseases

Disease-causing mutations may make proteins dysfunctional

Disease-causing mutations may involve any number of base pairs

Expanding triplet repeats demonstrate the fragility of some human genes

Cancer often involves somatic mutations

Most diseases are caused by multiple genes and environment

Mutations Can Be Detected and Analyzed

Cleavage of DNA by restriction enzymes can be used to rapidly detect mutations

Gel electrophoresis separates DNA fragments

DNA fingerprinting combines PCR with restriction analysis and electrophoresis

Archival tools Separating Fragments of DNA by Gel Electrophoresis

DNA analysis can be used to identify mutations that lead to disease

Genetic markers can be used to find disease-causing genes

Investigatinglife How Was the *BRCA1* Gene Identified?

Experiment

Working with the data

Genetic Screening Is Used to Detect Disease

Genetic screening can be done by examining the phenotype

DNA testing is the most accurate way to detect abnormal genes

Key tools DNA Testing by Allele-Specific Oligonucleotide Hybridization

Allele-specific oligonucleotide hybridization can detect mutations

Genetic Diseases Can Be Treated

Genetic diseases can be treated by modifying the phenotype

Gene therapy offers the hope of specific treatments

Ex Vivo Gene Therapy

Apply What You've Learned

16 Regulation of Gene Expression

Investigatinglife Gene Expression and Behavior

Prokaryotic Gene Expression Is Regulated in Operons

Regulating gene transcription conserves energy

Operons are units of transcriptional regulation in prokaryotes

Operator–repressor interactions control transcription in the lac and trp operons

Protein synthesis can be controlled by increasing promoter efficiency

RNA polymerases can be directed to particular classes of promoters

Eukaryotic Gene Expression Is Regulated by Transcription Factors

General transcription factors act at eukaryotic promoters

Specific proteins can recognize and bind to DNA sequences and regulate transcription

Specific protein–DNA interactions underlie binding

Transcription factors underlie cell differentiation

The expression of sets of genes can be coordinately regulated by transcription factors

Viruses Regulate Their Gene Expression during the Reproductive Cycle

Viruses undertake two kinds of reproductive cycles

Eukaryotic viruses can have complex life cycles

HIV gene regulation occurs at the level of transcription elongation

Epigenetic Changes Regulate Gene Expression

DNA methylation occurs at the promoter and silences transcription

Histone protein modifications affect transcription

Epigenetic changes can be induced by the environment

Investigatinglife Gene Expression and Behavior

Experiment

Work with the data

Global chromosome changes involve DNA methylation

Eukaryotic Gene Expression Can Be Regulated after Transcription

mRNA splicing can result in different mRNAs being made from the same gene

Small RNAs are important regulators of gene expression

Translation of mRNA can be regulated by proteins

Apply What You've Learned

PART FIVE Genomes

17 Genomes

Investigatinglife The Dog Genome Project

Genomes Can Be Sequenced Rapidly

The base sequence of a short DNA fragment can be determined quickly

Genome sequences yield several kinds of information

Investigatinglife Comparative Analysis of the Tiger Genome

Experiment

Work with the data

Prokaryotic Genomes Are Compact

Prokaryotic genomes have distinctive features

The sequencing of prokaryotic and viral genomes has many potential benefits

Metagenomics allows us to describe new organisms and ecosystems

Some sequences of DNA can move about the genome

Will defining the genes required for cellular life lead to artificial life?

Experiment Using Transposon Mutagenesis to Determine the Minimal Genome

Eukaryotic Genomes Contain Many Types of Sequences

Genome sequences of model organisms provide important information

Eukaryotes have gene families

Eukaryotic genomes contain repetitive sequences

Human Biology Is Revealed through the Genome

Comparative genomics reveals the evolution of the human genome

Human genomics has potential benefits in medicine

Proteomics and Metabolomics Can Provide Insights beyond the Genome

The proteome is the complete set of proteins in a cell, tissue, or organism at a given time

Metabolomics is the study of chemical phenotype

Apply What You've Learned

Recombinant DNA and Biotechnology

DNA Technology Meets Medicine

DNA from Different Sources Forms Recombinant DNA.

Experiment Can DNA from Two Different Sources Be Recombined into a Single Functional DNA Molecule?

There Are Several Ways to Insert DNA into Cells

Selectable genetic markers are used to identify host cells containing recombinant DNA

Genes can be inserted into prokaryotic or eukaryotic cells

Inserted DNA is usually integrated into the host chromosome

Reporter genes help select or identify host cells containing recombinant DNA

rich tools Selection for Recombinant DNA

Any Sequence of DNA Can Be Used for Cloning

DNA for cloning can come from a library

DNA is made from mRNA transcripts

Synthetic DNA can be made by PCR or by organic chemistry

rich tools Constructing Libraries

Several Tools Are Used to Modify DNA and Study Its Function

Gene expression can be modulated by DNA technology

DNA mutations can be created in the laboratory

Genes can be inactivated and changed by CRISPR technology

Complementary RNA can prevent the expression of specific genes

rich tools Inactivating or Mutating a Gene by CRISPR

DNA microarrays reveal RNA expression patterns

DNA Can Be Manipulated for Human Benefit

Cells can be turned into factories for a desired protein

Medically useful proteins can be made using biotechnology

DNA manipulation is changing agriculture

Producing TPA

Experiment

Work with the data

Synthetic biology can create living factories for new products

There is public concern about biotechnology

Apply What You've Learned

19 Genes, Development, and Evolution

Investigatinglife Stem Cell Therapy

The Four Major Processes of Development Are Determination, Differentiation, Morphogenesis, and Growth

Development involves four distinct but overlapping processes

As development proceeds cell fates become restricted

Cell differentiation is sometimes reversible

Experiment Cloning a Plant

Experiment Cloning a Mammal

Multipotent stem cells differentiate in response to environmental signals

Investigatinglife Stem Cell Therapy

Experiment

Work with the data

Pluripotent stem cells can be obtained in two ways

2 Gene Expression Differences Determine Cell Fate and Cell Differentiation

Cytoplasmic segregation can determine cell fate

Inducers passing from one cell to another can determine cell fate

Differential gene transcription is a hallmark of cell differentiation

3 Gene Expression Determines Morphogenesis and Pattern Formation

Morphogen gradients provide positional information

Expression of transcription factor genes determines organ differentiation in plants

A cascade of transcription factors establishes body segmentation in the fruit fly

4 Changes in Gene Expression Underlie the Evolution of Development

What is evo-devo?

Developmental genes in distantly related organisms are similar

Genetic switches govern how the genetic toolkit is used

Modularity allows for differences in the patterns of gene expression

5 Developmental Gene Changes Can Shape Evolution

Mutations in developmental genes can cause major morphological changes

Conserved developmental genes can lead to parallel evolution

Apply What You've Learned

Investigatinglife

An Evolutionary Arms Race Between Bats and Moths

Evolution Is Both Factual and the Basis of Broader Theory

Darwin and Wallace introduced the idea of evolution by natural selection

Mutation, Selection, Gene Flow, Genetic Drift, and Nonrandom Mating Result in Evolution

Mutation generates genetic variation

Selection acting on genetic variation leads to new phenotypes

Natural selection increases the frequency of beneficial mutations in populations

Investigatinglife

Do Long Wing Tails Help Moths Escape Bat Predation?

Experiment

Work with the data

Gene flow may change allele frequencies

Genetic drift may cause large changes in small populations

Nonrandom mating can change genotype or allele frequencies

Experiment Sexual Selection in Action

Evolution Can Be Measured by Changes in Allele Frequencies

Arch tools Calculating Allele and Genotype Frequencies

Mutation will occur unless certain restrictive conditions exist

Deviations from Hardy-Weinberg equilibrium show that evolution is occurring

Selection Can Be Stabilizing, Directional, or Disruptive

Stabilizing selection reduces variation in populations

Directional selection favors one extreme

Disruptive selection favors extremes over the mean

Multiple Factors Account for the Maintenance of Variation in Populations

Neutral mutations accumulate in populations

Sexual recombination amplifies the number of possible genotypes

Frequency-dependent selection maintains genetic variation within populations

Heterozygote advantage maintains polymorphic loci

Experiment A Heterozygote Mating Advantage

Work with the data A Heterozygote Mating Advantage

Genetic variation within species is maintained in geographically distinct populations

Evolution Is Constrained by History and Trade-Offs

Developmental processes constrain evolution

Trade-offs constrain evolution

Short-term and long-term evolutionary outcomes sometimes differ

Apply What You've Learned

21 Reconstructing and using Phylogenies

Investigatinglife Using Phylogeny to Improve a Genetic Tool

All of Life is Connected through its Evolutionary History

Phylogenetic trees are the basis of comparative biology

Derived traits provide evidence of evolutionary relationships

Phylogeny Can Be Reconstructed from Traits of Organisms

Parsimony provides the simplest explanation for phylogenetic data

Phylogenies are reconstructed from many sources of data

Mathematical models expand the power of phylogenetic reconstruction

The accuracy of phylogenetic methods can be tested

Investigatinglife Testing the Accuracy of Phylogenetic Analysis

Experiment

Work with the data

Phylogeny Makes Biology Comparative and Predictive

Phylogenetic trees can be used to reconstruct past events

Phylogenies allow us to compare and contrast living organisms

Phylogenies can reveal convergent evolution

Ancestral states can be reconstructed

Molecular clocks help date evolutionary events

Phylogeny Is the Basis of Biological Classification

Evolutionary history is the basis for modern biological classification

Several codes of biological nomenclature govern the use of scientific names

Apply What You've Learned

22 Speciation

Investigatinglife Rapid Speciation in African Lake Cichlids

Species Are Reproductively Isolated Lineages on the Tree of Life

We can recognize many species by their appearance

Reproductive isolation is key

The lineage approach takes a long-term view

The different species concepts are not mutually exclusive

Speciation Is a Natural Consequence of Population Subdivision

Incompatibilities between genes can produce reproductive isolation

Reproductive isolation develops with increasing genetic divergence

Speciation May Occur through Geographic Isolation or in Sympatry

Physical barriers give rise to allopatric speciation

Sympatric speciation occurs without physical barriers

Reproductive Isolation Is Reinforced When Diverging Species Come into Contact

Prezygotic isolating mechanisms prevent hybridization

Postzygotic isolating mechanisms result in selection against hybridization

Flower Color Reinforces a Reproductive Barrier in *Phlox*

Experiment

Work with the data

Hybrid zones may form if reproductive isolation is incomplete

Speciation Rates Are Highly variable across Life

Several ecological and behavioral factors influence speciation rates

Rapid speciation can lead to adaptive radiation

Apply What You've Learned

23

Evolution of Genes and Genomes

Evolutionary Theory helps us make Better Flu Vaccines

DNA Sequences Record the History of Gene Evolution

Evolution of genomes results in biological diversity

Genes and proteins are compared through sequence alignment

Search tools Amino Acid Sequence Alignment

Models of sequence evolution are used to calculate evolutionary divergence

Experimental studies examine molecular evolution directly

Genomes Reveal Both Neutral and Selective Processes of Evolution

Much of evolution is neutral

Positive and purifying selection can be detected in the genome

Phylogenetic Analysis of Molecular Evolution

with the data Convergent Molecular Evolution

Genome size also evolves

Lateral Gene Transfer and Gene Duplication Can Produce Major Changes

Lateral gene transfer can result in the gain of new functions

Most new functions arise following gene duplication

Some gene families evolve through concerted evolution

Molecular Evolution Has Many Practical Applications

Molecular sequence data are used to determine the evolutionary history of genes

Gene evolution is used to study protein function

In vitro evolution is used to produce new molecules

Molecular evolution is used to study and combat diseases

Why Was the 1918-1919 Influenza Pandemic So Severe?

Experiment

Work with the data

Apply What You've Learned

24

The history of Life on Earth

When Giant Insects Ruled the Skies

Events in Earth's History Can Be Dated

Radioisotopes provide a way to date fossils and rocks

Radiometric dating methods have been expanded and refined

Scientists have used several methods to construct a geological time scale

Changes in Earth's Physical Environment Have Affected the Evolution of Life

Earth's continents and climates have changed over time

Earth's climate has shifted between hot and cold conditions

Volcanoes have occasionally changed the history of life

Extraterrestrial events have triggered changes on Earth

Oxygen concentrations in Earth's atmosphere have changed over time

The Relationship between Atmospheric Oxygen Concentration and Body Size in Insects

Insects

Experiment

Work with the data

Extinction happens continuously, but mass extinctions result from sudden environmental changes

experiment What Factors Influence Extinction in Small Populations?

work with the data What Factors Influence Extinction in Small Populations?

Major Events in the Evolution of Life Can Be read in the Fossil Record

Several processes contribute to the paucity of fossils

Precambrian life was small and aquatic

Life expanded rapidly during the Cambrian period

Many groups of organisms that arose during the Cambrian later diversified

Geographic differentiation increased during the Mesozoic era

Modern biotas evolved during the Cenozoic era

The tree of life is used to reconstruct evolutionary events

Apply What You've Learned

PART SEVEN The Evolution of Diversity

25 Bacteria, Archaea, and Viruses

Investigatinglife Bacteria Light Up the Sea

Bacteria and Archaea Are the Two Primary Divisions of Life

The two prokaryotic domains differ in significant ways

The small size of prokaryotes has hindered our study of their evolutionary relationships

The nucleotide sequences of prokaryotes reveal their evolutionary relationships

Lateral gene transfer can lead to discordant gene trees

The great majority of prokaryote species have never been studied

Prokaryote Diversity Reflects the Ancient Origins of Life

Two early-branching lineages of bacteria live at very high temperatures

Firmicutes include some of the smallest cellular organisms

Actinobacteria include major pathogens as well as valuable sources of antibiotics

Cyanobacteria were the first photosynthesizers

Spirochetes move by means of axial filaments

Chlamydias are extremely small parasites

The proteobacteria are a large and diverse group

Gene sequencing enabled biologists to differentiate Archaea from Bacteria

Experiment What Is the Highest Temperature Compatible with Life?

work with the data What is the Highest Temperature Compatible with Life?

Prokaryotic archaea live in extremely diverse environments

Ecological Communities Depend on Prokaryotes

Many prokaryotes form complex communities

Microbiomes are critical to the health of many eukaryotes

Investigatinglife How Do Bacteria Communicate with One Another?

Experiment

A small minority of bacteria are pathogens

Prokaryotes have amazingly diverse metabolic pathways

Prokaryotes play important roles in element cycling

Viruses Have Evolved Many Times

Many RNA viruses probably represent escaped genomic components of cellular life

Some DNA viruses may have evolved from reduced cellular organisms

Viruses can be used to fight bacterial infections

Apply What You've Learned

26 The Origin and Diversification of Eukaryotes

Investigatinglife Predicting Toxic Red Tides

Eukaryotes Acquired Features from Both Archaea and Bacteria

The modern eukaryotic cell arose in several steps

Chloroplasts have been transferred among eukaryotes several times

Major Lineages of Eukaryotes Diversified in the Precambrian

Alveolates have sacs under their cell membranes

Stramenopiles typically have two unequal flagella, one with hairs

Experiment The Role of Vacuoles in Ciliate Digestion

Rhizarians typically have long, thin pseudopods

Excavates began to diversify about 1.5 billion years ago

Amoebozoans use lobe-shaped pseudopods for locomotion

Protists Reproduce Sexually and Asexually

Some protists reproduce without sex and have sex without reproduction

Some protist life cycles feature alternation of generations

Protists Are Critical Components of Many Ecosystems

Phytoplankton are primary producers

Some microbial eukaryotes are deadly

Some microbial eukaryotes are endosymbionts

We rely on the remains of ancient marine protists

Investigatinglife Can Corals Reacquire Dinoflagellate Endosymbionts Lost to Bleaching?

Experiment

Work with the data

Apply What You've Learned

27

Plants without Seeds: From Water to Land

Investigatinglife

A Toxic Spill of Ancient Fossil Algae

Primary Endosymbiosis Produced the First Photosynthetic Eukaryotes

Work with the data The Phylogeny of Land Plants

Several distinct clades of algae were among the first photosynthetic eukaryotes

Investigatinglife

Can *Chlorella* Algae Be Grown in Municipal Sewage Wastewater for Biofuel

Production?

Experiment

Work with the data

Two groups of green algae are the closest relatives of land plants

There are ten major groups of land plants

Key Adaptations Permitted Plants to Colonize Land

Adaptations to life on land distinguish land plants from green algae

Life cycles of land plants feature alternation of generations

Nonvascular land plants live where water is readily available

The sporophytes of nonvascular land plants are dependent on the gametophytes

Liverworts are the sister clade of the remaining land plants

Water and sugar transport mechanisms emerged in the mosses

Horsetails have distinctive chloroplasts and stalkless sporophytes

Vascular Tissues Led to Rapid Diversification of Land Plants

Vascular tissues transport water and dissolved materials

Vascular plants allowed herbivores to colonize the land

The closest relatives of vascular plants lacked roots

The lycophytes are sister to the other vascular plants

Horsetails and ferns constitute a clade

The vascular plants branched out

Heterospory appeared among the vascular plants

Experiment Atmospheric CO₂ Concentrations and the Evolution of Megaphylls

Apply What You've Learned

Brought Back from Extinction by a Seed

Pollen, Seeds, and Wood Contributed to the Success of Seed Plants

Features of the seed plant life cycle protect gametes and embryos

The seed is a complex, well-protected package

William Beal's Seed Viability Study

Experiment

Work with the data

A change in stem anatomy enabled seed plants to grow to great heights

Once Dominant Gymnosperms Still Thrive in Some Environments

There are four major groups of living gymnosperms

Conifers have cones and lack swimming sperm

Flowers and Fruits Led to Increased Diversification of Angiosperms

Angiosperms have many shared derived traits

The sexual structures of angiosperms are flowers

Flower structure has evolved over time

Angiosperms have coevolved with animals

The angiosperm life cycle produces diploid zygotes nourished by triploid endosperms

Experiment The Effect of Stigma Retraction in Monkeyflowers

Fruits aid angiosperm seed dispersal

Recent analyses have revealed the phylogenetic relationships of angiosperms

Plants Play Critical Roles in Terrestrial Ecosystems

Seed plants have been sources of medicine since ancient times

Seed plants are our primary food source

Apply What You've Learned

The Accidental Discovery of Antibiotics

Fungi Digest Food Outside Their Bodies

Yeasts are unicellular, free-living fungi

Multicellular fungi use hyphae to absorb nutrients

Fungi are in intimate contact with their environment

Fungi Are Decomposers, Parasites, Predators, or Mutualists

Saprobic fungi are critical to the planetary carbon cycle

Some fungi engage in parasitic or predatory interactions

Experiment What Is the Origin of Amphibian-Killing Chytrids in North America?

Mutualistic fungi engage in relationships that benefit both partners

Endophytic fungi protect some plants from pathogens, herbivores, and stress

Sex in Fungi Involves Multiple Mating Types

Fungi reproduce both sexually and asexually

Microsporidia are highly reduced, parasitic fungi

Most chytrids are aquatic

Some fungal life cycles feature separate fusion of cytoplasm and nuclei

Arbuscular mycorrhizal fungi form symbioses with plants

The dikaryotic condition is a synapomorphy of sac fungi and club fungi

The sexual reproductive structure of sac fungi is the ascus

The basidium is the sexual reproductive structure of club fungi

Fungi Have Many Practical Uses

Fungi are important in producing food and drink

Fungi provide important weapons against diseases and pests

Lichen diversity and abundance are indicators of air quality

Fungi record and help remediate environmental pollution

Reforestation may depend on mycorrhizal fungi

Fungi are used as model organisms in laboratory studies

Investigatinglife Using Fungi to Study Environmental Contamination

Experiment

Work with the data

Apply What You've Learned

30 Animal Origins and the Evolution of Body Plans

Investigatinglife A Mysterious Animal Discovered in an Aquarium

Some Animal Characteristics Evolved More Than Once

Animal monophyly is supported by gene sequences and morphology

A few basic developmental patterns differentiate major animal groups

Experiment What Induces Choanoflagellates to Form Multicellular Colonies?

Animals Diverged with Distinct Body Plans

Most animals are symmetrical

The structure of the body cavity influences movement

Segmentation improves control of movement

Appendages have many uses

Nervous systems coordinate movement and allow sensory processing

Animals Use Diverse Forms of Movement to Feed

Filter feeders capture small prey

Herbivores eat plants

Predators and omnivores capture and subdue prey

Parasites live in or on other organisms

Detritivores live on the remains of other organisms

Animal Life Cycles Involve Trade-Offs

Many animal life cycles feature specialized life stages

Most animal life cycles have at least one dispersal stage

Parasite life cycles facilitate dispersal and overcome host defenses

Some animals form colonies of genetically identical, physiologically integrated individuals

No life cycle can maximize all benefits

The Root of the Animal Tree Provides Clues to Early Animal Diversification

Ctenophores are the sister group of all other animals

Sponges are loosely organized animals

Investigatinglife

Reconstructing Animal Phylogeny from Protein-Coding Genes

Experiment

Work with the data

Placozoans are abundant but rarely observed

Cnidarians are specialized predators

Some small groups of parasitic animals may be the closest relatives of bilaterians

Apply What You've Learned

31

Protostome Animals

Investigatinglife

Exploring the Diversity of Life on Earth

Protostomes Account for More Than Half of All Described Species

Cilia-bearing lophophores and trochophores evolved among the lophotrochozoans

Ecdysozoans must shed their cuticles

Arrow worms retain some ancestral developmental features

Many Lophotrochozoans Have Ciliated Feeding Structures or Life Stages

Most bryozoans and entoprocts live in colonies

Flatworms, rotifers, and gastrotrichs are structurally diverse relatives

Ribbon worms have a long, protrusible feeding organ

Brachiopods and phoronids use lophophores to extract food from the water

Annelids have segmented bodies

Mollusks have undergone a dramatic evolutionary radiation

Ecdysozoans Grow by Shedding Their Cuticles

Several marine ecdysozoan groups have relatively few species

Nematodes and their relatives are abundant and diverse

Arthropods Are the Most Abundant and Diverse Group of Animals

Arthropod relatives have fleshy, unjointed appendages

Jointed appendages appeared in the trilobites

Chelicerates have pointed, nonchewing mouthparts

Mandibles and antennae characterize the remaining arthropod groups

More than half of all described species are insects

How Many Unknown Species?

Experiment

Work with the data

Features of Protostome Evolution

Apply What You've Learned

32

Deuterostome Animals

Which Came First, the Chicken or the Egg?

Deuterostomes Include Echinoderms, Hemichordates, and Chordates

Deuterostomes share early developmental patterns

There are three major deuterostome clades

Fossils shed light on deuterostome ancestors

Echinoderms and Hemichordates Are Restricted to Marine Environments

Echinoderms have unique structural features

Hemichordates are wormlike marine deuterostomes

Chordates Have a Dorsal Nerve Cord and a Notochord

Adults of most lancelets and tunicates are sedentary

A dorsal supporting structure replaces the notochord in vertebrates

The phylogenetic relationships of jawless fishes are uncertain

Jaws and teeth improved feeding efficiency

Fins and swim bladders improved stability and control over locomotion

Life on Land Contributed to Vertebrate Diversification

- Jointed limbs enhanced support and locomotion on land
- Amphibians usually require moist environments
- Amniotes colonized dry environments
- Reptiles adapted to life in many habitats

Investigatinglife

Have Shelled Eggs Re-Evolved among Viviparous Reptile Lineages?

Experiment

Work with the data

- Crocodylians and birds share their ancestry with the dinosaurs
- Feathers allowed birds to fly
- Mammals radiated after the extinction of non-avian dinosaurs

Humans Evolved among the Primates

- Two major lineages of primates split late in the Cretaceous
- Bipedal locomotion evolved in human ancestors
- Human brains became larger as jaws became smaller
- Humans developed complex language and culture

Apply What You've Learned

PART EIGHT Flowering Plants: Form and Function

33 The Plant Body

Investigatinglife

Bread of the Tropics

The Plant Body Is Organized in a Distinctive Way

- Most angiosperms are either monocots or eudicots
- Plants develop differently than animals
- Apical-basal polarity and radial symmetry are characteristics of the plant body

Plant Organs Are Made Up of Three Tissue Systems

- The dermal tissue system forms the outer covering of a plant
- The ground tissue system makes up most of the plant body
- The vascular tissue system develops into the plant's transport system

Meristems Build a Continuously Growing Plant

- How do plants increase in size?
- Meristems generate the plant body
- Indeterminate primary growth originates in apical meristems

The root apical meristem gives rise to the root cap and the root primary meristems
The products of the root's primary meristems become root tissues
The root system anchors the plant and takes up water and dissolved minerals
The products of the stem's primary meristems become stem tissues
The stem supports leaves and flowers but can have other roles
Leaves are determinate organs produced by shoot apical meristems
Many stems and roots undergo secondary growth

Investigatinglife Understanding the Synthesis and Transport of Cyanogenic Glycosides

Experiment

Work with the data

Domestication Has Altered Plant Form

Apply What You've Learned

34 Transport in Plants

Investigatinglife Thirsty Rice

Plants acquire Water and Minerals from the Soil

Water potential differences govern the direction of water movement
Water and ions move across the root cell's cell membrane
Water and ions pass to the xylem by way of the apoplast and symplast

Water and Minerals Are Transported in the Xylem

Various hypotheses have proposed how water moves in the xylem
The transpiration-cohesion-tension mechanism accounts for xylem transport

Investigatinglife Improving Water-Use Efficiency in Rice

Experiment

Work with the data

Stomata Control the Loss of Water and the Uptake of CO₂

Stomata control water loss and gas exchange
The guard cells control the size of the stomatal opening

Solutes Are Transported in the Phloem

Sucrose and other solutes are carried in the phloem
The pressure flow model accounts for translocation in the phloem

Apply What You've Learned

Plants Require Nutrients

- Plants require nutrients in different amounts
- Deficiency symptoms reveal inadequate nutrition
- Hydroponic experiments identified essential elements

Plants Acquire Nutrients from the Soil

- Plants rely on growth to find nutrients
- Nutrient uptake and assimilation are regulated

Soil Structure Affects Plant Nutrition

- Soil provides anchorage and nutrients for plants
- Soils form through the weathering of rock
- Soils are the source of plant nutrition
- Fertilizers add nutrients to soil

Soil Organisms Increase Nutrient Uptake by Plant Roots

- Plants send signals to soil organisms
- Mycorrhizae expand the root system
- Soil bacteria are essential in getting nitrogen from air to plant cells
- Nitrogenase catalyzes nitrogen fixation

Experiment

Work with the data

- Biological nitrogen fixation does not always meet agricultural needs
- Ammonia formation is the first step in nitrogen assimilation by plants

Carnivorous and Parasitic Plants Obtain Nutrients in Unique Ways

- Carnivorous plants supplement their mineral nutrition
- Parasitic plants take advantage of other plants
- The plant-parasite relationship is similar to plant-fungus and plant-bacteria associations

Apply What You've Learned

Plants Develop in Response to the Environment

Plant growth is regulated

In early development, the seed germinates and forms a growing seedling

Several hormones and photoreceptors help regulate plant growth

Genetic screens have increased our understanding of plant signal transduction

rich tools A Genetic Screen

Gibberellins and Auxin Have Diverse Effects but a Similar Mechanism of Action

Gibberellins have many effects on plant growth and development

Auxin plays a role in differential plant growth

Investigatinglife The Darwins' Phototropism Experiment

Experiment

Work with the data

Auxin affects plant growth in several ways

At the molecular level, auxin and gibberellins act similarly

Other Plant Hormones Have Diverse Effects

Cytokinins are active from seed to senescence

Ethylene is a gaseous hormone that hastens leaf senescence and fruit ripening

Brassinosteroids are plant steroid hormones

Photoreceptors Initiate Developmental Responses to Light

What are plant photoreceptors?

Phototropins, cryptochromes, and zeaxanthin are blue-light receptors

Phytochromes mediate the effects of red and far-red light

Experiment Sensitivity of Seeds to Red and Far-Red Light

Work with the data Sensitivity of Seeds to Red and Far-Red Light

Phytochrome stimulates gene transcription

Circadian rhythms are entrained by light reception

Apply What You've Learned

37 **Reproduction in Flowering Plants**

Investigatinglife What Signals Flowering?

Most Angiosperms Reproduce Sexually

How does the flower function as a structure for sexual reproduction?

Flowering plants have microscopic gametophytes

A pollen tube delivers sperm cells to the embryo sac

Many flowering plants control pollination or pollen tube growth to prevent inbreeding

Angiosperms perform double fertilization

Embryos develop within seeds contained in fruits

Seed development is under hormonal control

Hormones and Signaling Determine the Transition from the Vegetative to the Reproductive State

Flowering occurs at specific places and specific times

A cascade of gene expression leads to flowering

Photoperiodic cues can initiate flowering

Plants vary in their responses to photoperiodic cues

Light length is a key photoperiodic cue that determines flowering

The flowering stimulus originates in a leaf

Investigatinglife The Flowering Signal

Experiment

Work with the data

Experiment The Flowering Signal Moves from Leaf to Bud

Work with the data The Flowering Signal Moves from Leaf to Bud

Florigen is a small protein

Flowering can be induced by temperature or gibberellin

Some plants do not require an environmental cue to flower

Angiosperms Can Reproduce Asexually

Plants reproduce asexually by several methods

Vegetative reproduction has a disadvantage

Vegetative reproduction is important in agriculture

In apomixis, flowers are used in asexual reproduction

Apply What You've Learned

38 Plant Responses to Environmental Challenges

Investigatinglife Can Scientists Breed Disease-Resistant Wheat?

Plants Respond to Pathogens with Constitutive and Induced Responses

Physical barriers form constitutive defenses

Plants can seal off infected parts to limit damage

General and specific immunity both involve multiple responses

Investigatinglife A Gene for Resistance to Wheat Rust

Experiment

Work with the data

Specific immunity is genetically determined

Specific immunity usually leads to the hypersensitive response

Systemic acquired resistance is a form of long-term immunity

Plants Have Mechanical and Chemical Defenses against Herbivores

Plants have mechanical defenses against herbivores

Plants produce constitutive chemical defenses against herbivores

Plants respond to herbivory with induced defenses

jasmonates trigger a range of responses to wounding and herbivory

Plants don't always win the arms race

Plants Can Adapt to Environmental Stresses

Plants can adapt to dry conditions

Some plants grow in saturated soils

Plants can respond to drought stress

Plants can cope with temperature extremes

Plants can adapt to salty soil

Some plants can tolerate heavy metals

Apply What You've Learned

PART NINE Animals: Form and Function

39 Physiology, Homeostasis, and Temperature Regulation

Investigatinglife Heat Limits Physical Performance

Animals Are Composed of Organs Built from Four Types of Tissues

How would you build a multicellular animal?

There are advantages and challenges to getting bigger

There are four tissue types

Organs are built from multiple tissues

Physiological Systems Maintain Homeostasis of the Internal Environment

The internal environment is the extracellular fluid that serves all the needs of the cells of the body

Physiological systems are regulated to maintain homeostasis

Biological Processes Are Temperature-Sensitive

Temperature affects living systems

Q_{10} is a measure of temperature sensitivity

Animals acclimatize to seasonal temperatures

Small changes in temperature can have large physiological effects

Experiment

Work with the data

Body Temperature Depends on the Balance between Heat In and Heat Out of the Body

Animals can be classified by their thermoregulatory characteristics

Endotherms produce substantial amounts of metabolic heat

Ectotherms and endotherms respond differently to changes in environmental temperature

Energy budgets reflect adaptations for regulating body temperature

Both ectotherms and endotherms control blood flow to the skin

Some fish conserve metabolic heat

Some ectotherms regulate metabolic heat production

Body Temperature Is Regulated through Adaptations for Heat Production and Heat Loss

Basal heat production rates of endotherms correlate with body size

Endotherms respond to cold by producing heat and adapt to cold by reducing heat loss

Evaporation of water can dissipate heat, but at a cost

The mammalian thermostat uses feedback information

Some animals conserve energy by turning down the thermostat

Experiment The Hypothalamus Regulates Body Temperature

Apply What You've Learned

40

Animal Hormones

Hormones Circulate Around the Body and Affect Target Cells

There are multiple chemical communication systems in the body

Endocrine signaling can act locally or at a distance

Hormones are divided into three chemical groups

Hormone action is mediated by receptors on or within their target cells

Hormone action depends on the nature of the target cell and its receptors

Hormone structure is conserved through evolution, but functions change

The Endocrine System and Nervous System Work Together

The pituitary is an interface between the nervous and endocrine systems

Hypothalamic neurohormones control the anterior pituitary

egative feedback loops regulate hormone secretion

ormones influence the nervous system

How Could Irisin Mediate the Benefits of Exercise on Cognition?

periment

with the data

Hormones Play Important Roles in Development

insect development consists of either complete or incomplete metamorphosis

Experiments on insect development revealed hormonal signaling systems

Three hormones regulate molting and maturation in arthropods

Sex steroids control sexual development

Hormones Regulate Metabolism and the Internal Environment

Thyroxine stimulates many metabolic processes

Three hormones regulate blood calcium concentrations

PTH lowers blood phosphate levels

Insulin and glucagon regulate blood glucose concentrations

ment Effects of Exercise on Glucose Metabolism

with the data Effects of Exercise on Glucose Metabolism

The adrenal gland is two glands in one

Many chemicals may act as hormones

The pineal gland has a daily cycle of melatonin release

Apply What You've Learned

41

Immunology: Animal Defense

Vaccines and Immunity

Animals Use Innate and Adaptive Mechanisms for Defense

Innate defenses evolved before adaptive defenses

Mammals have both innate and adaptive defenses

Blood and lymph tissues play important roles in defense

White blood cells play many defensive roles

Immune system proteins bind pathogens or signal other cells

Innate Defenses Are Nonspecific

Specialized proteins and cells participate in innate immunity

Inflammation is a coordinated innate response to infection or injury

Adaptive Defenses Are Specific

What are the key features of adaptive immunity?

Macrophages and dendritic cells play a key role in activating the adaptive immune system
Two types of adaptive immune responses interact
Adaptive immunity develops as a result of clonal selection
Clonal deletion helps the immune system distinguish self from nonself
Immunological memory results in a secondary immune response
Vaccines are an application of immunological memory

What Are the Mechanisms and Implications of Long-Lasting Immunity?

Experiment

Work with the data

The Humoral Adaptive Response Involves Antibodies

Antibody protein structure reflects function
There are five classes of immunoglobulins
Immunoglobulin diversity results from DNA rearrangements and other mutations
The constant region is involved in immunoglobulin class switching

The Cellular Adaptive Response Involves T Cells and Receptors

MHC proteins present antigen to T cells, causing recognition
T-helper cells and MHC II proteins contribute to the humoral immune response
Cytotoxic T cells and MHC I proteins contribute to the cellular immune response
Regulatory T cells suppress the humoral and cellular immune responses

Malfunctions in Immunity Can Be Harmful

The immune system mounts an excessive response in allergic reactions
Autoimmune diseases are caused by reactions against self antigens
AIDS is an immune deficiency disorder

Apply What You've Learned

Animal Reproduction

No Time to waste

Asexual Reproduction is Efficient but Limits Genetic Variability

Asexual reproduction limits genetic diversity
Budding and regeneration produce new individuals by mitosis
Parthenogenesis is the development of unfertilized eggs

Sexual Reproduction Involves the Union of Haploid Egg and Sperm

Gametogenesis produces eggs and sperm
Fertilization is the union of sperm and egg
Spawning and mating behaviors get eggs and sperm together

Some individuals can function as both male and female

The evolution of vertebrate reproductive systems parallels the move to land

Animals with internal fertilization are distinguished by where the embryo develops

Male Sex Organs Produce and May Deliver Sperm

Semen is the product of the male reproductive system

The penis and the scrotum are the male external genitalia

Male sexual function is controlled by hormones

Female Sex Organs Produce Eggs and Nurture Embryos

Ovarian cycles produce mature eggs

The uterine cycle prepares an environment for a fertilized egg

Hormones control and coordinate the ovarian and uterine cycles

LH receptors determine which follicle ovulates

In pregnancy, hormones from the extraembryonic membranes take over

Breast feeding delays the return of the ovarian cycle

Childbirth is triggered by hormonal and mechanical stimuli

Investigatinglife The Control of Diapause in the Tammar Wallaby

Experiment

Go with the data

Birth as well as reproduction is timed

Fertility Can Be Controlled

Humans use a variety of methods to control fertility

Reproductive technologies help solve problems of infertility

Apply What You've Learned

43

Animal Development

Investigatinglife Go With the Flow

Fertilization Activates Development

The sperm and the egg make different contributions to the zygote

Fertilization sets the stage for determination

Mitosis Divides up the Early Embryo

Cleavage produces a multicellular embryo

Cleavage in mammals is unique

The fates of blastomeres depend on the cytoplasm they receive during cleavage

Reproductive germ cells are determined early in cleavage

Gastrulation Generates Multiple Tissue Layers

Invagination at the vegetal pole initiates gastrulation in the sea urchin
 frog gastrulation begins at the gray crescent
 The dorsal lip of the blastopore organizes the formation of the amphibian embryo
 Transcription factors and growth factors underlie the organizer's actions
 Properties of organizer cells change as they migrate from the dorsal lip
 Experiment The Dorsal Lip Induces Embryonic Organization
 The amount of yolk influences gastrulation
 Gastrulation in mammals is similar to avian gastrulation
 How is bilateral symmetry broken?

Investigatinglife Does the Direction of Nodal Flow Influence the Development of Left-Right symmetry in the Mouse Embryo?

Experiment

Work with the data

Organs Develop from the Three Germ Layers

The organizer sets the stage for organogenesis
 Body segmentation is an early feature of vertebrate development
 Hox genes control differentiation along the anterior-posterior axis

Extraembryonic Membranes Nurture Avian and Mammalian Embryos

Birds develop four extraembryonic membranes
 The mammalian placenta forms from extraembryonic membranes
 Human gestation is divided into trimesters

Apply What You've Learned

14

Neurons, Glia, and Nervous Systems

Investigatinglife Balancing the Brain

Neurons and Glia Are Unique Cells of Nervous Systems

Vertebrate neurons and macroglia originate in the embryonic neural tube
 The structure of neurons reflects their functions
 Glia are the “silent partners” of neurons

Neurons Generate and Transmit Electric Signals

Simple electrical concepts underlie neuronal function
 Activities of neurons are recorded as changes in membrane potential
 Research tools Measuring the Membrane Potential
 Ion transporters and channels generate membrane potentials
 Ion channels and their properties can be studied directly

rich tools Using the Nernst Equation

Gated ion channels alter membrane potential

with the data Equilibrium Membrane Potential: The Goldman Equation

rich tools Patch Clamping

Graded changes in membrane potential can integrate information

Sudden changes in Na^+ and K^+ channels generate action potentials

Action potentials are conducted along axons without loss of signal

Action potentials jump along myelinated axons

Neurons Communicate with Other Cells

The neuromuscular junction is a model chemical synapse

The arrival of an action potential causes the release of neurotransmitter

Synaptic functions involve many proteins

The postsynaptic membrane responds to neurotransmitter

Synapses can be excitatory or inhibitory

The postsynaptic neuron sums excitatory and inhibitory input

Electrical synapses are fast but do not integrate information well

The action of a neurotransmitter depends on the receptor to which it binds

To turn off responses, synapses must be cleared of neurotransmitter

Investigatinglife Can Learning Be Restored in Mouse Models of Down Syndrome?

Experiment

Work with the data

The diversity of receptors makes drug specificity possible

Neurons and Glia Form Information-Processing Circuits

Nervous systems range in complexity

Reflexes are controlled by simple circuits involving sensory neurons, interneurons, and effectors

The vertebrate brain is the seat of behavioral complexity

Apply What You've Learned

45 Sensory Systems

Investigatinglife Seeing in the Dark

Sensory Receptor Cells Convert Stimuli into Action Potentials

Sensory transduction involves changes in membrane potentials

Sensory receptor proteins act on ion channels

Sensation depends on which neurons receive action potentials from sensory cells

Many receptors adapt to repeated stimulation

Experiment

Work with the data

Chemoreceptors Respond to Specific Molecules

Olfaction is the sense of smell

Some chemoreceptors detect pheromones

The vomeronasal organ contains chemoreceptors

Gustation is the sense of taste

Mechanoreceptors Respond to Physical Forces

Many different receptor cells respond to touch and pressure

Mechanoreceptors are also found in muscles, tendons, and ligaments

Hair cells are mechanoreceptors of the auditory and vestibular systems

Auditory systems use hair cells to sense sound waves

Flexion of the basilar membrane is perceived as sound

Various types of damage can result in hearing loss

The vestibular system uses hair cells to detect forces of gravity and momentum

Photoreceptors Respond to Light

Vertebrates have a variety of visual systems

Image-forming eyes evolved independently in vertebrates and cephalopods

The vertebrate retina receives and processes visual information

Opsins are the universal photoreceptor molecule in animals

Rod and cone cells are the photoreceptors of the vertebrate retina

Experiment How Light Stimulates Rod Cells

Information flows through layers of neurons in the retina

Apply What You’ve Learned

46

The Mammalian Nervous System: Structure and Higher Functions

Functions Are Localized in the Nervous System

Functional organization is based on flow and type of information

The anatomical organization of the CNS emerges during development

The spinal cord transmits and processes information

The brainstem carries out many autonomic functions

The core of the forebrain controls physiological drives, instincts, and emotions

The cerebrum is responsible for complex behavior and consciousness

Experiment

Work with the data

The size of the human brain is off the curve

Nervous System Functions Rely on Neural Circuits

Pathways of the autonomic nervous system control involuntary physiological functions

The visual system is an example of information integration by the cerebral cortex

Three-dimensional vision results from cortical cells receiving input from both eyes

Experiment What Does the Eye Tell the Brain?

Higher Brain Functions Involve Integration of Multiple Systems

Sleep and dreaming are reflected in electrical patterns in the cerebral cortex

Language abilities are localized in the left cerebral hemisphere

Some learning and memory can be localized to specific brain areas

We still cannot answer the question “What is consciousness?”

Apply What You’ve Learned

47

Musculoskeletal Systems

Interactions of Actin and Myosin Cause Muscles to Contract

Sliding filaments of actin and myosin cause skeletal muscle to contract

Actin-myosin interactions cause filaments to slide

Actin-myosin interactions are controlled by calcium ions

Cardiac muscle is similar to and different from skeletal muscle

Smooth muscle causes slow contractions of many internal organs

Many Factors Affect Muscle Performance

The strength of a muscle contraction depends on how many fibers are contracting and at what rate

Muscle fiber types determine endurance and strength

A muscle has an optimal length for generating maximum tension

Experiment

Work with the data

Exercise increases muscle strength and endurance

Muscle ATP supply limits performance

Work with the data Does Heat Cause Muscle Fatigue?

nsect muscle has the greatest rate of cycling

Muscles and Skeletal Systems Work Together

A hydrostatic skeleton consists of fluid in a muscular cavity

Exoskeletons are rigid outer structures

Vertebrate endoskeletons consist of cartilage and bone

Bones develop from connective tissues

Bones that have a common joint can work as a lever

Apply What You've Learned

Gas Exchange

The Breath of Life

Respiratory Gas Exchange is Governed by Physical Factors

Diffusion of gases is driven by partial pressure differences

Fick's law applies to all systems of gas exchange

Air is a better respiratory medium than water

High temperatures create respiratory problems for aquatic animals

O₂ availability decreases with altitude

CO₂ is lost by diffusion

Enhancing Diffusion Maximizes Respiratory Gas Exchange

Respiratory organs have large surface areas

Ventilation and perfusion of gas exchange surfaces maximize partial pressure gradients

Insects have airways throughout their bodies

Fish gills use countercurrent flow to maximize gas exchange

Birds use unidirectional ventilation to maximize gas exchange

Tidal ventilation produces dead space that limits gas exchange efficiency

Arch Tools Measuring Lung Ventilation

With the data Measuring Lung Ventilation

Small residual volume prevents the bends in seals

Humans Have Tidal Respiration

Lungs are ventilated through a branching system of airways

Respiratory tract secretions aid ventilation

Lungs are ventilated by pressure changes in the thoracic cavity

Respiratory Gases Are Transported by the Blood

Red blood cells are produced in the bone marrow

Hemoglobin combines reversibly with O₂

Myoglobin holds an O₂ reserve

Hemoglobin's affinity for O₂ is variable

Investigatinglife **Seals Are Champion Breath-hold Divers**

Experiment

Work with the data

Most CO₂ is transported as bicarbonate ions in the blood

Breathing Is Homeostatically Regulated

Breathing is controlled in the brainstem

Regulating breathing requires feedback

Apply What You've Learned

49 Circulatory Systems

Investigatinglife **Athletes with Big Hearts**

Circulatory Systems Serve Many Functions

Some animals do not have a circulatory system

Circulatory systems can be open or closed

Open circulatory systems move extracellular fluid

Closed circulatory systems circulate blood through a system of blood vessels

Vertebrate Circulatory Systems Evolved from Single to Double Circuits

Circulation in fishes is a single circuit

Lungfishes evolved a gas-breathing organ

Amphibians have partial separation of systemic and pulmonary circulation

Reptiles have exquisite control of pulmonary and systemic circulation

Birds and mammals have fully separated pulmonary and systemic circuits

Heart Function Depends on Properties of Cardiac Muscle

Blood flows from right heart to lungs to left heart to body

The heartbeat originates in the cardiac muscle

A conduction system coordinates the contraction of heart muscle

ECM can disrupt conduction

Investigatinglife **Silencing Mutant Myosin Genes**

Experiment

Work with the data

Electrical properties of ventricular muscles sustain heart contraction

The ECG records the electrical activity of the heart

Circulatory System Functions Depend on Blood and Blood Vessels

Red blood cells transport respiratory gases

Platelets are essential for blood clotting

Arteries withstand high pressure, arterioles control blood flow

Materials are exchanged in capillary beds by filtration, osmosis, and diffusion

Blood flows back to the heart through veins

Lymphatic vessels return interstitial fluid to the blood

Vascular disease is a killer

The Circulation is Controlled by Hormonal and Neural Signals

Autoregulation matches local blood flow to local need

Arterial pressure is regulated by hormonal and neural mechanisms

Apply What You've Learned

50 Nutrition, Digestion, and Absorption

Investigatinglife Thrifty Phenotypes

Food Provides Energy As Well As Materials for Biosynthesis

Energy needs and expenditures can be measured

Sources of energy are stored in the body

Food provides carbon skeletons for biosynthesis

Animals need mineral elements for a variety of functions

Animals must obtain vitamins from food

Nutrient deficiencies result in diseases

Diverse Adaptations Support Ingestion and Digestion of Food

The food of herbivores is often low in energy and hard to digest

Carnivores must find, capture, and kill prey

Vertebrate species have distinctive teeth

Digestion usually begins in a body cavity

Tubular guts have an opening at each end

Digestive enzymes break down complex food molecules

The gut microbiome contributes to digestion

Investigatinglife How Does the Gut Microbiome Contribute to Obesity and Metabolic Disease?

Experiment

Work with the data

The Vertebrate Gastrointestinal System is a Disassembly Line

The vertebrate gut consists of concentric tissue layers

But motility moves food through the gut and aids digestion
Chemical digestion begins in the mouth and the stomach
The stomach gradually releases its contents to the small intestine
Most chemical digestion occurs in the small intestine
Nutrients are absorbed in the small intestine
Absorbed nutrients go to the liver
Water and ions are absorbed in the large intestine
Herbivores rely on their microbiota to digest cellulose

Nutrient Availability is Controlled and Regulated

Hormones control many digestive functions
The liver stores and releases the molecules that fuel metabolism
The liver produces lipoproteins: the good, the bad, and the ugly
Insulin and glucagon control fuel metabolism
The brain plays a major role in regulating food intake
Experiment A Single-Gene Mutation Leads to Obesity in Mice

Apply What You've Learned

51

Salt and Water Balance and Nitrogen Excretion

Investigatinglife How Vampire Bats Use Blood as Fast Food

Excretory Systems Regulate Osmotic and Ionic Concentrations

Osmosis causes water to enter or to leave cells
Excretory systems control extracellular fluid osmolarity and composition
Aquatic invertebrates are either ionic conformers or regulators
Vertebrates are osmoregulators and ionic regulators

Animals Excrete Nitrogen as Ammonia, Urea, or Uric Acid

Ammonia is toxic
Urea is highly soluble in water
Uric acid is not very soluble in water
Most species produce more than one nitrogenous waste

Invertebrate Excretory Systems Use Filtration, Secretion, and Reabsorption

Protonephridia of flatworms excrete water and conserve salts
Metanephridia of annelids process coelomic fluid
Malpighian tubules of insects use active transport to excrete wastes

The Nephron Is the Basic Functional Unit of Vertebrate Excretory Systems

Marine fishes must conserve water

Terrestrial amphibians and reptiles must avoid desiccation

Mammals can produce highly concentrated urine

The nephron is the functional unit of the vertebrate kidney

Blood is filtered into Bowman's capsule

The renal tubules convert glomerular filtrate to urine

The Mammalian Kidney Can Produce Concentrated Urine

Kidneys produce urine and the bladder stores it

Nephrons have a regular arrangement in the kidney

Most of the glomerular filtrate is reabsorbed by the proximal convoluted tubule

The loop of Henle creates a concentration gradient in the renal medulla

Investigatinglife

How Can Vampire Bats Use Blood as Fast Food?

Experiment

Work with the data

Water permeability of kidney tubules depends on water channels

The distal convoluted tubule fine-tunes the composition of the urine

Urine is concentrated in the collecting duct

The kidneys help regulate acid-base balance

Kidney failure is treated with dialysis

Kidney Function Is Regulated

Glomerular filtration rate is regulated

Regulation of GFR uses feedback information from the distal tubule

Blood osmolarity and blood pressure are regulated by ADH

The heart produces a hormone that helps lower blood pressure

Experiment ADH Induces Insertion of Aquaporins into Cell Membranes

Apply What You've Learned

52

Animal Behavior

Investigatinglife

An Instinct to Learn

Ethology Led to Modern Behavioral Biology

Conditioned reflexes are a simple behavioral mechanism

Ethologists focused on the behavior of animals in their natural environment

Ethologists probed the causes of behavior

Behavior Can Be Genetically Determined

Single gene mutations can alter behavioral phenotypes

Knockout experiments reveal the roles of specific genes

Gene cascades can control complex behavioral phenotypes

Behavior Can Be Studied Developmentally

Hormones can determine behavioral potential and timing

Some behaviors can be acquired only at certain times

Birdsong learning involves genetics, imprinting, development, and social interactions

Investigatinglife Practice Makes Perfect

Experiment

Work with the data

The timing and expression of birdsong are under hormonal control

Selective Pressures Shape Behavior

Animals are faced with many choices

Behaviors have costs and benefits

Territorial behavior carries significant costs

Experiment The Costs of Defending a Territory

Foraging behavior has costs and benefits

Behavior Can Be Studied Mechanistically

Biological rhythms coordinate behavior with environmental cycles

Animals must find their way around their environment

Animals use multiple modalities to communicate

Experiment A Time-Compensated Solar Compass

Social Interactions Shape the Evolution of Behavior

Mating systems evolve to maximize fitness

Fitness can include more than your own offspring

Eusociality is the extreme result of kin selection

Group living has benefits and costs

Can the concepts of sociobiology be applied to humans?

Apply What You've Learned

PART TEN Ecology

53

The Physical Environment and Biogeography of Life

Investigatinglife The Largest Experiment on Earth

Ecology Is the Study of the Interrelationships among Organisms and the Environment

Modern ecology has a more “use-inspired” focus

Ecology is studied at many levels of organization

Answering ecological questions requires observations, experiments, and models

Global Climate Is a Fundamental Component of the Physical Environment

Solar radiation drives global climate patterns

Earth is a sphere, creating latitudinal variation in global temperature and precipitation

Earth spins on an axis, producing prevailing winds and ocean currents

The tilt of Earth’s axis and its orbit result in seasons

Topography, Vegetation, and Humans Modify the Physical Environment

Earth’s topography affects the local and regional physical environment

Vegetation affects the local and regional physical environment, especially climate

Humans have transformed their physical environment, including urban climate

Biogeography Is the Study of How Organisms Are Distributed on Earth

Patterns of biogeography are interconnected across a hierarchy of spatial and temporal scales

Terrestrial biomes reflect global patterns of temperature and precipitation

Biogeographic regions reflect evolutionary isolation

Diversity varies with latitude and longitude

Geographic variation in diversity is explained by multiple factors

Geographic Area and Humans Affect Regional Species Diversity

Humans exert a powerful influence on biogeographic patterns

Investigatinglife The Largest Experiment on Earth

Experiment

Work with the data

Apply What You’ve Learned

54 Populations

Investigatinglife Earth’s Human Carrying Capacity

Populations Show Dynamic Variation in Size over Space and Time

Population dynamics are controlled by the physical environment, biological interactions, and dispersal

Ecologists use a variety of approaches to estimate population size and extent

Research tools The Mark-Recapture Method

Work with the data Monitoring Tick Populations

Population Growth Describes the Change in Population Size over Time

Births increase and deaths decrease population size over time

All populations have the potential for exponential growth

Will the Global Human Population Growth Rate Decline?

Experiment

Work with the data

Logistic growth occurs as a population approaches its carrying capacity

Factors limiting population growth can be density-dependent or density-independent

Life tables keep track of demographic events

Life History Is the Lifetime Pattern of Growth, Reproduction, and Survival

Life history strategies can vary at species and population levels

Life history strategies arise from constraints on growth, reproduction, and survival

Population Biology Can Be Used in Conserving and Managing Populations

Management plans must take life history strategies into account

Management plans must be guided by the principles of population dynamics

Knowledge of metapopulation dynamics helps us conserve species

Apply What You've Learned

55

Species Interactions

The Lionfish King

Species Interactions Vary in Direction and Strength across a Continuum

Species interactions are not always clear-cut

Some interactions result in evolutionary change in the species involved

Predation Is a Trophic Interaction in which Predators Benefit and Prey Are Harmed

Carnivory results in a range of capture and avoidance mechanisms

Herbivory is a widespread but specialized interaction

The Lionfish King

Experiment

Work with the data

Most parasites specialize on hosts, and most hosts house many species of parasites

Predator populations can cycle with their prey populations

Predators can have dramatic effects on communities

Competition is a Negative Interaction in which Species Overlap in the Use of Some Limiting Resource

Resource partitioning allows species to coexist despite overlapping use of limiting resources

The physical environment, disturbance, and predation can each alter the outcome of competition

Competition can affect species' distributions

Positive Interactions Occur When at Least One Species Benefits and None Are Harmed

Positive interactions are more common in stressful environments

Positive interactions can have dramatic effects on populations and communities

Experiment: Are Ants and Acacia Mutualists?

Apply What You've Learned

56 Communities

Investigatinglife Rising from the Ashes

Communities Are Groups of Interacting Species Occurring Together in Space and Time

Ecologists often use a subset of species to define communities

Species diversity and composition are important descriptors of community structure

Community Membership Depends on Species Supply, Environmental Conditions, and Species Interactions

Community membership depends on species supply

Environmental conditions are critical to community membership

Resident species can restrict or promote community membership

Communities Are Complex Networks of Species Interactions That Vary in Strength and Direction

Indirect interactions are important to community structure

Strongly interacting species often regulate community structure

Species with similar effects on one another may coexist by chance

Communities Are Always Changing

Change in communities can be caused by abiotic and biotic factors

Succession is a process of change in communities over time

Both facilitation and inhibition influence succession

Investigatinglife Rising from the Ashes

Experiment

Work with the data

Alternative successional pathways result in variations in community composition

Relationships between Species Diversity and Community Function Are Often Positive

Species diversity is associated with productivity and stability

Diversity, productivity, and stability differ between natural and managed communities

Apply What You've Learned

57 Ecosystems

Investigatinglife Food webs in an Acidic and warming ocean

Ecosystem Science Considers How Energy and Nutrients Flow through Biotic and Abiotic Environments

Energy flowing through ecosystems originates with sunlight and inorganic and organic compounds

Nutrients cycling through ecosystems originate in soil, water, and the atmosphere

Energy and Nutrients in Ecosystems Are First Captured by Primary Producers

Net primary production is the amount of carbon remaining in plants after respiration

Patterns of primary production vary with latitude and ecosystem type

Rainfall and temperature largely control terrestrial primary production

Light and nutrients combine to control aquatic primary production

Food Webs Transfer Energy and Nutrients from Primary Producers to Consumers

The amount of energy transferred within food webs depends on trophic efficiency

Food webs are controlled by bottom-up and top-down forces

The number of trophic levels can control the flow of energy through food webs

Nutrient Cycling in Ecosystems Involves Chemical and Biological Transformations

Water cycles rapidly around the globe

The carbon cycle is being altered by human activities, resulting in climate change

The nitrogen cycle is dominated by biotic processes

Investigatinglife Food Webs in an Acidic and Warming Ocean

Experiment

Work with the data

The global phosphorus cycle is dominated by geochemical processes

The burning of fossil fuels affects the sulfur cycle

Ecosystems Provide Important Services and Values to Humans

The value of ecosystem services can be measured

Apply What You've Learned

58 A Changing Biosphere

Investigatinglife Fatal Fungus Final Fate for Frogs

Human Activities Are Changing the Biosphere, Resulting in Biodiversity Loss

Biodiversity has great value to human society

Diversity loss at one scale affects diversity loss at other scales

Species diversity is being lost at unprecedented rates

We can predict the effects of human activities on biodiversity

Most Biodiversity Loss Is Caused by Habitat Loss and Degradation

Habitat loss and degradation endanger species

Overharvesting has driven many species to extinction and changed food webs

Invasive predators, competitors, and pathogens threaten many species

Investigatinglife Exploring the Decline of Central American Frogs

Experiment

Work with the data

Species and ecosystems are already being affected by climate change

Protecting Biodiversity Requires Conservation and Management Strategies

Protected areas preserve habitat and curtail biodiversity loss

Degraded ecosystems can be restored

Captive breeding programs can maintain a few species

Ending trade is crucial to saving some species

Species invasions must be controlled or prevented

Biodiversity can be conserved as a consequence of its economic value

investigatinglife

Corals in Hot Water

Coral reefs support the largest diversity of life in the oceans. They provide fisheries and storm protection for about a billion people, and are a magnificent source of natural beauty. But coral reefs are endangered. Over the past 20 years about half of the world's reef-building corals have been destroyed by rising water temperature and other factors. High temperatures disrupt a fascinating aspect of coral biology. Corals are animals, yet most corals have algae (dinoflagellates) growing within their cells. Dinoflagellates use the energy of sunlight to produce carbohydrates. Corals provide a home for the dinoflagellates, which in turn provide nutrients for the corals. When high temperature impairs the dinoflagellates, the corals eject them—a process called bleaching. Then, without nutrients from the dinoflagellates, the corals die, unless they can take in new dinoflagellates that are more resistant to the higher temperatures.

Understanding the effects of heat on corals was the motivation of graduate student Rachael Bay and her colleagues working with Professor Steve Palumbi at Stanford University's Hopkins Marine Station. While studying corals in small backreef pools in American Samoa, they observed that during low tides some pools reached higher temperatures than others. The researchers predicted that corals in the warmer pools had mechanisms enabling them to resist bleaching. To test their prediction, the researchers brought corals into the laboratory, subjected them to temperature fluctuations, and showed that the corals from the warm pools were more resistant to bleaching. They also transplanted corals between the different temperature environments in nature. As a result of these experiments, Rachael and her colleagues proposed that two different processes contribute to the different abilities of the corals to survive heat stress. First, corals growing in the warmer pools could have genetic traits contributing to heat resistance, and second, individual corals may have the same genetic make-up but differ in their ability to adjust to their environment by changing the expression levels of certain genes. More knowledge of the mechanisms of heat stress and heat resistance in corals could lead to new strategies to decrease their losses as their environments change.

How might experiments on heat stress in corals be used to predict the response of corals to global warming?

1.1 Living Organisms Share Similarities and a Common Origin

Intuitively we all know what life is, but try to define it; it isn't easy. You can easily designate the things around you as living or nonliving, but what are the essential differences? We call the living things organisms. In contrast to nonliving things, organisms sustain and renew themselves. The loss of the ability to sustain and renew means the loss of life, and organisms that die become part of the nonliving world. **Biology** is the scientific study of organisms, both living and after death (e.g., the study of fossils) with the goal of discovering and understanding the diversity and the complex processes that make up life.

focus your learning

Major characteristics are shared among all living things.

Living organisms have influenced the history of the planet Earth.

Biological populations change over time.

Life on our planet is quite diverse ([Figure 1.1](#)), yet its many diverse forms share common features. What characteristics do organisms share that distinguish them from the nonliving world? Most organisms:

are composed of a common set of chemical compounds: mainly carbohydrates, fatty acids, nucleic acids, and amino acids.

are made up of cells.

use molecules obtained from the environment to synthesize new biological molecules.

extract energy from the environment and use it to do work.

contain genetic information—genomes—that enables them to develop, maintain themselves, function, and reproduce.

use a universal molecular code to build proteins from their genomic information.

regulate their internal environments.

exist in populations that evolve over time.

(A) *Sulfolobus*

(B) *Escherichia coli*

(C) *Coronosphaera mediterranea*

(D) *Thelocactus conothelos argenteus*

(E) *Pholiota squarrosa* (shaggy scalycap mushrooms)

(F) *Heteractis magnifica* (magnificent sea anemone) *Eretmochlys imbricata* (hawksbill turtle) *Chaetodon punctatofasciatus* (spotband butterflyfish)

Figure 1.1 The Many Faces of Life The processes of evolution have led to the millions of diverse organisms living on Earth today. Prokaryotic archaea (A) and bacteria (B) are all single-celled organisms, as described in [Chapter 25](#). (C) Many protists are unicellular but, as discussed in [Chapter 26](#), their cell structures are more complex than those of the prokaryotes. This protist has manufactured “plates” of calcium carbonate that surround and protect its single cell. (D–F) Most of the visible life on Earth is multicellular. [Chapters 27](#) and [28](#) cover the green plants (D). The other broad groups of multicellular organisms are the fungi (E), discussed in [Chapter 29](#),

and the animals (**F**), covered in [Chapters 30–32](#).

How do you think all organisms came to have these similarities? If life had multiple origins, we would not expect to see such striking similarities in chemical composition, cell structure, cell functions, and genetic codes across the living world. Instead, these common characteristics logically lead to the conclusion that all life has a common ancestry, and that the diverse organisms alive today all originated from one life form. Organisms from a separate origin of life—say, on another planet—might be similar in superficial ways to life on Earth, but they would not have the same genetic code, chemical composition, or cellular structures and functions that we see widely shared among living organisms on Earth. All evidence points to a common origin of life on our planet about 4 billion years ago.

Some forms of life may not display all characteristics listed above all of the time. For example, the seed of a desert plant may go for many years without extracting energy from the environment, converting molecules, regulating its internal environment, or reproducing; yet the seed is alive. Viruses present a special case as well. Viruses are not composed of cells and cannot carry out physiological functions on their own. Viruses depend on the cells of host organisms to carry out these functions for them. Yet viruses contain genetic information, and their populations evolve over time, as we know from witnessing changes in the flu viruses each flu season. Even though viruses are not independent cellular organisms, their existence depends on cells, and it is highly probable that viruses evolved from cellular life forms. Thus most biologists consider viruses to be a part of life.

As you go through this book, you will explore details of the common characteristics of life, how these characteristics arose, and how they work together so that organisms survive and reproduce. Because organisms do not all survive and reproduce with equal success, you will see again and again that through differential survival and reproduction populations of organisms evolve and become adapted to Earth's many environments. The processes of evolution have generated the enormous diversity of life on Earth, and evolution is a central theme of biology.

Life arose from non-life via chemical evolution

Earth formed between 4.6 and 4.5 billion years ago, but it was not a place hospitable to life. The cooling of Earth, the formation of surface water, and the evolution of the first life forms took about 600 million years. If we picture the 4.6-billion-year history of Earth as a 30-day month, life first appeared some time around the end of the first week ([Figure 1.2](#)).

Figure 1.2 Life's Timeline Depicting the 4.6 billion years of Earth's history on the scale of a 30-day month provides a sense of the immensity of evolutionary time.

The young Earth's atmosphere, oceans, and climate were very different than they are today, but experiments simulating those conditions have confirmed that the generation of complex molecules through random physical association of chemicals is possible, even inevitable. The critical step for the evolution of life was the appearance of **nucleic acids**—molecules that could reproduce themselves and serve as templates for the synthesis of **proteins**, large molecules with complex but stable shapes. The variation in the shapes of these proteins enabled them to participate in increasing numbers and kinds of chemical reactions with other molecules. These subjects are covered in [Part One](#) of this book.

nucleic acid (new klay' ik) A polymer made up of nucleotides, specialized for the storage, transmission, and expression of genetic information. DNA and RNA are nucleic acids.

protein (pro' teen) [Gk. *protos*: first] Long-chain polymer of amino acids with twenty different common side chains. Occurs with its polymer chain extended in fibrous proteins, or coiled into a compact macromolecule in enzymes and other globular proteins. The component amino acids are encoded in the triplets of messenger RNA, and proteins are the products of genes.

Cellular structure evolved in the common ancestor of life

An important step in the evolution of life was the enclosure of complex proteins and other biological molecules by membranes that contained them in a compact internal environment separate from the surrounding (external) environment. Fatty acid molecules played a critical role in membrane evolution because these molecules do not dissolve in water. Think of shaking an oil and vinegar salad dressing. The oil breaks up into small droplets, but the droplets do not dissolve in the vinegar and they rapidly coalesce. Similarly, fatty acids can form membranous films on the surface of water. When these films are agitated, they can form spherical structures called **liposomes**. Such structures are now used for delivering drugs to cells ([Figure 1.3A](#)). In a primordial ocean, such membranous structures could have enveloped assemblages of complex biological molecules. The origin of an internal environment that concentrated reactants and products of chemical reactions led to the first cells with the ability to replicate themselves—the evolution of the first cellular organisms.

liposome (lip' o zome) Spherical structure contained by a membrane of phospholipids. Can be used to deliver drugs to cells.

200 nm

(A) Liposomes

(B) Prokaryotic cells

(C) Eukaryotic cells

Figure 1.3 Cells Are Building Blocks for Life These photographs were taken with electron microscopes (see [Figure 5.3](#)) and enhanced with added color to highlight details. (A) Liposomes are tiny round bubbles known as vesicles and are made out of the same material as a cell membrane. Liposomes can be filled with drugs and used to deliver drugs to cells. (B) Two prokaryotic cells of an *Enterococcus* bacterium that lives in the human digestive system. Prokaryotes are unicellular organisms with genetic and biochemical material enclosed inside a single membrane. (C) A human white blood cell (lymphocyte) represents one of the many specialized cell types that make up a multicellular eukaryote. Multiple membranes within the cell-enclosing outer membrane segregate the different biochemical processes of eukaryotic cells.

For billions of years all the organisms existing on Earth were unicellular and were enclosed by a single outer membrane. Such organisms, like the bacteria that are abundant on you, in you, and all around you, are called [prokaryotes](#) ([Figure 1.3B](#)). Two main groups diverged early in life's history: the **Bacteria** and **Archaea**. The third major category of life on earth, the **Eukarya**, arose billions of years later from one group of archaea. In addition to its outer membrane, a eukaryotic cell ([Figure 1.3C](#)) has internal membranes that enclose specialized internal compartments called organelles. The organelle that gives eukaryotes their name is the [nucleus](#) — the organelle that contains the cell's genetic information. The word “eukaryote” comes from two Greek words meaning “a true kernel.” Other organelles carry out specific functions such as synthesizing biological molecules or providing energy.

prokaryotes Unicellular organisms that do not have nuclei or other membrane-enclosed organelles. Includes Bacteria and Archaea. (Contrast with eukaryotes.)

nucleus (new' klee us) [L. *nux*: kernel or nut] (1) In cells, the centrally located compartment of eukaryotic cells that is bounded by a double membrane and contains the chromosomes.

(2) In the brain, an identifiable group of neurons that share common characteristics or functions.

How might eukaryotes have arisen from prokaryotes? Infoldings of the prokaryote cell membrane could have formed internal compartments—the organelles—that isolated cell functions from each other, resulting in greater integration or efficiency of cell functions. Another possibility, similar to that seen in the relationship between corals and dinoflagellates described at the beginning of this chapter, is that close, interdependent relationships may have developed between different prokaryote cells, leading to a merger of sorts. Suppose a prokaryote good at converting energy was engulfed (but not digested) by a prokaryote good at synthesizing biological molecules. Each would supply a valuable service for the other, but now one would be an organelle inside the other. The structure of prokaryote and eukaryote cells, their membranes, and their evolution are the subjects of [Part Two](#).

Single-celled organisms were the only forms of life for over half of the history of life on Earth (see [Figure 1.2](#)). However, at some point the cells of some eukaryotes didn't separate after cell division, instead they remained attached to each other. Such colonial aggregations of cells made it possible for some of the associated cells to specialize in certain functions, such as reproduction, while other cells specialized in other functions, such as absorbing nutrients or motility. This [cellular specialization](#) enabled multicellular eukaryotes to increase in size and become more efficient at gathering resources and adapting to specific environments.

cellular specialization In multicellular organisms, the division of labor such that different cell types become responsible for different functions (e.g., reproduction or digestion) within the organism.

Photosynthesis allows some organisms to capture energy from the sun

Living cells require energy to function. The earliest prokaryotes supplied their energy needs—their [metabolism](#)—by taking in small molecules from their environment, breaking the chemical bonds of these molecules, and using the energy released from those chemical bonds to do cellular work. Many modern prokaryotes still function this way, and they function very successfully. But about 2.5 billion years ago, the emergence of [photosynthesis](#) changed the nature of life on Earth.

metabolism (meh tab' a lizm) [Gk. *metabole*: change] The sum total of the chemical reactions that occur in an organism, or some subset of that total (as in respiratory metabolism).

photosynthesis (foe tow sin' the sis) [Gk. creating from light] Metabolic processes carried out by green plants and some microorganisms by which visible light is trapped and the energy used to synthesize compounds such as ATP and glucose.

Photosynthesis transforms the energy of sunlight into a form of [*chemical energy](#) that can be used to do work such as the synthesis of large molecules. These large molecules can then be used to build cell structures or can be broken down to provide metabolic energy. Photosynthesis is the basis of much of life on Earth today because its energy-capturing processes provide food for other organisms. Early photosynthetic cells were probably similar to present-day prokaryotes called **cyanobacteria** ([Figure 1.4](#)). Over time, photosynthetic prokaryotes became so abundant that vast quantities of oxygen gas (O₂), which is a by-product of photosynthesis, began to accumulate in the atmosphere.

(A) Cyanobacteria

(B) Fossilized stromatolite

(C) Living stromatolite

Figure 1.4 Photosynthetic Organisms Changed Earth's Atmosphere (A)

Cyanobacteria are aquatic and photosynthetic: they live in the water and can manufacture their own food. Although they are quite small, they often grow in colonies large enough to see. **(B)** Colonies of photosynthetic cyanobacteria and other microorganisms produced structures called stromatolites that were preserved in the ancient fossil record. This section of fossilized stromatolite reveals layers representing centuries of growth. **(C)** Living stromatolites can still be found in appropriate environments.

During the early history of prokaryotic life, there was no O_2 in Earth's atmosphere. In fact, O_2 was toxic to many of the prokaryotes living at that time, and its buildup in the atmosphere resulted in a huge mass extinction. But those organisms that could tolerate O_2 proliferated. Atmospheric O_2 opened up vast new avenues of evolution because **aerobic metabolism**—a biochemical process that uses O_2 to extract energy from nutrient molecules—is far more efficient than **anaerobic metabolism** (which does not use O_2). Most organisms today use aerobic metabolism.

Oxygen in the atmosphere also made it possible for life to move onto land. For most of life's history, UV radiation falling on Earth's surface was so intense that it destroyed any organism that was not shielded by water. The atmospheric accumulation of photosynthetically generated O_2 over a period of more than 2 billion years gradually produced a thick layer of ozone (O_3) in the upper atmosphere. By about 500 million years ago, the ozone layer was sufficiently dense and absorbed enough of the sun's UV radiation to make it possible for organisms to leave the protection of the water and live on land.

Biological information is stored in a genetic code common to all organisms

Before there was a science of biology, humans recognized that offspring resemble parents, and this fact was used by plant and animal breeders to produce variants with desirable qualities. However, not until the famous plant breeding experiments of the Austrian monk Gregor Mendel in the mid-1800s was it demonstrated that inherited traits existed in discrete units (**Figure 1.5**). These discrete units of inheritance were termed **genes** in the early 1900s, giving rise to the science of **genetics**. An enormous body of information about traits of organisms represented by

single genes was created before the chemical structure of a gene was known, and hence before the nature of the information that is passed from parent to offspring was known. That mystery was solved in the mid-1900s with the discovery that the molecule deoxyribonucleic acid, **DNA**, is the genetic information that specifies what an organism will look like and how it will function. This “blueprint” for the existence of each individual organism is contained in the sum total of all the DNA molecules contained in each of the organism’s cells—its **genome**. DNA molecules are long sequences of four different subunits called **nucleotides**. Genes are specific segments of DNA that encode the information the cell uses to build proteins. Therefore each gene is defined by a specific sequence of the four nucleotides. The genetic code spells out how sequences of nucleotides are ***translated** into sequences of amino acids, which are the building blocks of proteins. This translation process involves first **transcribing** some of the DNA information of a gene into the structure of another smaller molecule called **ribonucleic acid (RNA)** (**Figure 1.6**). RNA serves as the template for synthesis of a protein. Protein molecules govern the chemical reactions within cells and form much of an organism’s structure.

Figure 1.5 Genetics Developed as the Study of Discrete Heritable Traits Gregor Mendel discovered the basics of genetics through breeding experiments with pea

plants. When he crossed tall plants with short plants, all of the offspring were tall. Then when he crossed these offspring plants, he got one short plant for every three tall plants. From these experiments Mendel concluded that there was a tall factor and a short factor. Each plant inherited one factor from each parent, and the tall factor was dominant.

Figure 1.6 DNA Is Life's Blueprint The instructions for life are contained in the sequences of nucleotides in DNA molecules. Specific DNA nucleotide sequences compose genes. The average length of a single human gene is 16,000 nucleotides. The information in each gene provides the cell with the information it needs to manufacture molecules of a specific protein.

gene [Gk. *genes*: to produce] A unit of heredity. Used here as the unit of genetic function which carries the information for a polypeptide or RNA.

genetics The scientific study of the structure, functioning, and inheritance of genes, the units of hereditary information.

DNA (deoxyribonucleic acid) The fundamental hereditary material of all living organisms. In eukaryotes, stored primarily in the cell nucleus. A nucleic acid using deoxyribose rather than ribose.

genome (jee' nome) The complete DNA sequence for a particular organism or individual.

nucleotide The basic chemical unit in nucleic acids, consisting of a pentose sugar, a phosphate group, and a nitrogen-containing base.

By analogy with a book, the nucleotides of DNA are like the letters of an alphabet, and protein molecules are the words. Combinations of proteins that form structures and control specific biochemical processes are the sentences and paragraphs. The structures and processes that are organized into different complex systems with specific tasks (such as digestion or movement) are the chapters of the book, and the complete book is the organism. If you were to write out your own genome using four letters to represent the four nucleotides, you would write more than 3 billion letters. Using the size type you are reading now, your genome would fill about 1,000 books the size of this one. The processes of evolution are the authors and editors of all the books in the library of life.

Even though all the cells of a multicellular organism contain essentially the same genome, different cells of the organism have different functions and form different structures—contractile proteins form in muscle cells, hemoglobin in red blood cells, digestive enzymes in gut cells, and so on. We thus surmise that different types of cells in an organism express different parts of the genome. How cells control gene expression to enable a complex organism to develop and function is a major focus of current biological research.

The genome of an organism consists of thousands of genes. This entire genome must be replicated as new cells are produced. However, the replication process is not perfect, and a few errors, known as [mutations](#), are likely to occur when the genome is replicated. Mutations occur spontaneously and can be induced by environmental factors such as chemicals and radiation. Most mutations are either harmful or have no effect, but occasionally a mutation improves the functioning of the organism under the environmental conditions it encounters.

mutation A change in the genetic material not caused by recombination.

The discovery of the structure of DNA by James Watson and Francis Crick in the middle of the twentieth century, and the subsequent elucidation of the mechanisms by which this material encodes and transmits information, transformed biology. These crucial discoveries are detailed in Parts Four and Five of this book.

Populations of all living organisms evolve

A [population](#) is a group of individuals of the same type of organism that interbreed. The processes of [evolution](#) result in changes in the genetic makeup of populations through time. Evolution is the major unifying principle of biology. Charles Darwin compiled factual evidence for evolution in his 1859 book *On the Origin of Species*. Darwin argued that differential survival and reproduction among individuals in a population, which he termed [*natural selection](#), could account for much of the evolution of biodiversity.

population (1) In biology, any group of organisms coexisting at the same time and in the same place and capable of interbreeding with one another. (2) In statistics, a study group of interest.

evolution Any gradual change. Most often refers to organic or Darwinian evolution, which is the genetic and resulting phenotypic change in populations of organisms from generation to generation. (See macroevolution, microevolution. Contrast with speciation.)

Although Darwin proposed that all organisms are descended from a common ancestor and therefore are related to one another, he did not have knowledge of the mechanisms of genetic inheritance. Even so, he understood the process of selective breeding of plants and animals to obtain breeds with desired traits. Darwin himself was a pigeon breeder and knew that he could produce pigeons with different colorations, feather patterns, or tail shapes by selecting mates (see [Figure 20.5](#)). The steps in such selective breeding can be described as follows:

Observe trait variation in a population.

Selectively breed pairs based on a desired trait to produce that trait in their offspring.

Repeat such crosses in subsequent generations to amplify the trait.

Darwin realized that if humans could select for specific traits in domesticated plants and animals, the same process could operate in nature; hence the term “natural selection” as opposed to artificial (human-imposed) selection. He reasoned that the reproductive capacity of plants and animals, if unchecked, would result in unlimited growth of populations, but we do not observe such growth in nature. In most species, only a small percentage of an individual's offspring survive to reproduce. Thus any trait that confers even a small increase in the probability that its possessor will survive and reproduce increases in the population across generations.

Because organisms with certain traits survive and reproduce best under specific sets of conditions, natural selection leads to **adaptations**: structural, physiological, or behavioral traits that enhance an organism's chances of survival and reproduction in its environment ([Figure 1.7](#)). The opening story of this chapter described experiments aimed at understanding adaptations that might enable corals to survive in a warmer environment. In addition to natural selection, evolutionary processes such as sexual selection (selection due to mate choice) and genetic drift (the random fluctuation of gene frequencies in a population due to chance events) contribute to biodiversity. These processes operating over evolutionary history have contributed to the remarkable diversity of life on Earth. [Part Six](#) describes how natural selection and other evolutionary processes are supported and explained by the massive body of genetic and molecular genetic knowledge mostly produced over the past hundred years.

adaptation (a dap tay' shun) (1) In evolutionary biology, a particular structure, physiological process, or behavior that makes an organism better able to survive and reproduce. Also, the evolutionary process that leads to the development or persistence of such a trait. (2) In sensory neurophysiology, a sensory cell's loss of sensitivity as a result of repeated stimulation.

(A) *Dyscophus guineti*

(B) *Pelophylax* sp.

(C) *Hyloscirtus lindae*

(D) *Rhacophorus nigropalmatus*

Figure 1.7 Adaptations to the Environment The limbs of frogs show adaptations to the different environments of each species. **(A)** This terrestrial frog walks across the ground using its short legs and peglike digits (toes). **(B)** Webbed rear feet are evident in this highly aquatic species of frog. **(C)** This arboreal species has toe pads, which are adaptations for climbing. **(D)** A different arboreal species has extended webbing between the toes, which increases surface area and allows the frog to glide from tree to tree.

Over most of the history of biology, the diversity of life was described and catalogued based on structural characteristics of organisms. With the rapid development of molecular genetic tools in recent years, it is now possible to obtain the DNA sequences of parts or all of the genomes of organisms. Now it is possible to compare organisms on the basis of their DNA blueprints, which has given rise to the field of [genomics](#). For example, a structural feature that differentiates humans with African or European origins versus East Asian origins is hair. Europeans have fine hair that can be curly, as is the hair of Africans. East Asians have thick hair that is straight. This difference is due to a gene called *EDAR* and to a single nucleotide substitution in that gene resulting in a single amino acid change in the protein product of that gene ([Figure 1.8](#)).

genomics The scientific study of entire sets of genes and their interactions.

East Asian

African

East Asian	TCCACGTACAACCTCTGAGAAGGCTG	T	TGTGAAAACGTGGCGCCACCTCGCC
African	TCCACGTACAACCTCTGAGAAGGCTG	C	TGTGAAAACGTGGCGCCACCTCGCC

Figure 1.8 The Blueprint of Life Using technologies that reveal the sequence of nucleotides that make up the genome of an organism, we can detect small alterations that are responsible for specific traits. The *EDAR* gene is involved in hair development, and a single nucleotide substitution results in a single amino acid difference between the EDAR proteins of humans with Asian origins and those with African or European origins.

The ability to sequence the billions of letters in genetic codes generates enormous amounts of data, and to manage and analyze that data, the field of **bioinformatics** has grown in parallel with genomics. Genomics has enormous applications throughout biology, from evolutionary studies to investigations of human health. Advances in genomics and bioinformatics make current initiatives in precision medicine possible.

bioinformatics The use of computers and/or mathematics to analyze complex biological information, such as DNA sequences.

Biologists trace the evolutionary tree of life

Populations geographically isolated from one another evolve differences. As populations diverge from one another, individuals from one population become less likely to reproduce successfully with individuals of the other populations. Eventually these differences between the populations become so great that they are considered to be different species. Thus species that share a fairly recent evolutionary history are generally more similar to each other than are species that share an ancestor in the more distant past. By identifying, analyzing, and quantifying similarities and differences among species, biologists can construct **phylogenetic trees** that portray the evolutionary histories of the different groups of organisms. As an example, we can show the evolutionary relationships among humans and our closest living relatives in a branching diagram that shows how they diverged from a common ancestor. In this tree, the living species are shown at the tips of the branches, and the branches show when these groups diverged from one another along a time scale. Our convention in this book will be to place phylogenetic trees on their sides, with the oldest lineages on the left and the most recent to the right.

phylogenetic tree A graphic representation of these lines of evolutionary descent.

Tens of millions of species exist on Earth today; many times that number lived in the past but are now extinct. Biologists give each of these species a distinctive scientific name formed from two Latinized names—a **binomial**. The first part of the name identifies the species' **genus** (plural *genera*)—a group of species that share a recent common ancestor. The second part of the scientific name identifies a particular species within the genus. For example, the scientific name for modern-day humans is *Homo sapiens*: *Homo* is our genus, *sapiens* refers to our species. *Homo* is Latin for “man,” and *sapiens* is from the Latin word for “wise” or “rational.” The binomial for our close but extinct relatives, the Neanderthals, is *Homo neanderthalensis*. Note that it is conventional to write the binomial in italics with the genus capitalized but the second part not capitalized.

genus (jean' us) (plural: genera) [Gk. *genos*: stock, kind] A group of related, similar species recognized by taxonomists with a distinct name used in binomial nomenclature.

Much of biology is based on comparisons among species. Meaningful interpretations of those comparisons require an understanding of evolutionary relationships of the respective species. Our ability to reconstruct evolutionary relationships has been greatly enhanced in recent decades by gene sequencing. Genomic sequence analysis and other molecular techniques have enabled biologists to augment evolutionary knowledge based on the fossil record with a vast array of molecular evidence. The result is the ongoing compilation of phylogenetic trees that document and diagram evolutionary relationships. The broadest categories of the tree of life are shown in [Figure 1.9](#), and they will be surveyed in more detail in [Part Seven](#). (The tree is expanded in [Appendix A](#), and you can also explore the tree interactively online.)

Figure 1.9 The Tree of Life The earliest division of life was between the Bacteria and Archaea. Later, one lineage of Archaea incorporated specializations (including a cell nucleus) that allowed the repeated evolution of multicellularity; we call this specialized group Eukarya. The aqua branches within Eukarya represent various groups of microbial eukaryotes, more commonly known as “protists.” The organisms on any one branch share a common ancestor.

Q: According to this phylogenetic tree, are fungi more closely related to plants or to animals?

See the **Interactive Tree of Life** www.Life11e.com/tree

Although many details remain to be clarified, the broad outlines of the tree of life have been determined. Its branching patterns are based on a rich array of evidence from fossils, structures, metabolic processes, behavior, and molecular analyses of genomes. Recall that the primary division of life—into Archaea and Bacteria—occurred among the early single-celled prokaryotes. Members of these two groups differ so fundamentally that they are believed to have separated into distinct evolutionary lineages early in the history of life. One of the lineages of Archaea incorporated a nucleus and internal, membrane-bound organelles and gave rise to the major group Eukarya. Plants, fungi, and animals are examples of familiar multicellular eukaryotes that evolved independently, from different groups of the unicellular eukaryotes known as **protists**. We know that plants, fungi, and animals had independent origins of multicellularity because each of these three groups is most closely related to different groups of protists, as can be seen from the branching pattern of [Figure 1.9](#).

Cellular differentiation and specialization underlie multicellular life

Single-celled organisms must provide for all of their own needs, but the cells of multicellular organisms can evolve specializations to carry out certain functions exclusively and efficiently because they can depend on other cells to carry out other functions. Thus the cells of a multicellular organism can have different developmental fates. Similar cell types can develop

together into **tissues** that accomplish tasks that a single cell cannot. For example, muscle cells develop cellular mechanisms for generating force. A single muscle cell cannot generate much force, but many cells of a muscle tissue can work together to generate considerable force, and working with structural tissues such as bones, they can produce large movements. Different tissue types develop together into **organs** that accomplish specific functions. The heart, brain, and stomach are each composed of several types of tissues, as are the roots, stems, and leaves of plants. Organs whose functions are interrelated can be grouped into **organ systems**; the esophagus, stomach, and intestines, for example, are all part of the digestive system. The hierarchy of biological organization from atom to organism is shown in **Figure 1.10A**. The biology of the two major groups of multicellular organisms, plants and animals, is discussed in detail in Parts Eight and Nine, respectively.

tissue A group of similar cells organized into a functional unit; usually integrated with other tissues to form part of an organ.

organ [Gk. *organon*: tool] A body part, such as the heart, liver, brain, root, or leaf. Organs are composed of different tissues integrated to perform a distinct function. Organs, in turn, are integrated into organ systems.

organ system An interrelated and integrated group of tissues and organs that work together in a physiological function.

Figure 1.10 Biology Is Studied at Many Levels of Organization (A) Life's properties emerge when DNA and other molecules are organized in cells, which form building blocks for organisms. **(B)** Organisms exist in populations and interact with other populations to form communities, which interact with the physical environment to make up the many ecosystems of the biosphere.

Activity 1.1 The Hierarchy of Biological Organization www.Life11e.com/ac1.1

Organisms extract energy and raw materials from the environment

Living organisms acquire nutrients from the environment. Biochemical reactions break down complex nutrient molecules into smaller chemical units. Some of those smaller units are used as building blocks for structures the organism requires. The breakdown of nutrient molecules does more than supply raw materials. The breaking of the chemical bonds of nutrient molecules releases energy that the cell transfers to high-energy molecules that it uses to do work.

One kind of work cells do is mechanical—moving molecules from one cellular location to another, moving whole cells or tissues, or even moving the organism itself (**Figure 1.11A**). The cell also does biochemical work in the building, or synthesis, of new complex molecules and structures from smaller chemical units. For example, we are all familiar with the fact that carbohydrates eaten today may be deposited in the body as fat tomorrow (**Figure 1.11B**). Still another kind of work is the electrical work that is the essence of information processing in nervous systems.

(A) *Coracias garrulus*

(B) *Spermophilus parryi*

Figure 1.11 Energy Can Be Used Immediately or Stored (A) Animal cells break down food molecules and use the energy contained in the chemical bonds of those molecules to do mechanical work, such as running, flying, and jumping. This image is a European roller flying with mammal prey in its bill. (B) The cells of this Arctic ground squirrel have broken down the complex carbohydrates in the plants it consumed and converted those molecules into fats. The fats are stored in the animal's body to provide an energy supply for the cold months.

The many biochemical reactions that take place in cells are integrally linked in that the products of one reaction are the raw materials of the next. These complex networks of reactions must be integrated and precisely controlled; when they are not, the result is malfunction and disease.

Living organisms must regulate their internal environment

If different specialized cells, tissues, and organs provide for different needs of the multicellular organism, how are these specific services shared by the cells of the whole organism? All of the cells of the body share an **internal environment** that is made up of extracellular fluids. Cells derive their nutrients from these extracellular fluids, and they deposit their wastes into the extracellular fluid. This internal environment serves the needs of all cells of the body, and therefore its physical and chemical composition must be maintained within a narrow range of physiological conditions that support survival and function. The maintenance of this narrow range of conditions is known as **homeostasis**. A relatively stable internal environment means that cells can function efficiently even when external conditions could not support the lives of individual cells.

internal environment In multicellular organisms, includes blood plasma and interstitial fluid (i.e., the extracellular fluids that surround the cells).

homeostasis (home' ee o sta' sis) [Gk. *homos*: same + *stasis*: position] The maintenance of a steady state, such as a constant temperature, by means of physiological or behavioral feedback responses.

***Homeostasis** requires that the activities of the cells and systems of the body be regulated. Regulation requires information—information about internal conditions, external conditions, and what is optimal. Thus organisms must have **sensory mechanisms** to monitor conditions, **effector mechanisms** to alter those conditions, and **signaling mechanisms** to integrate information and enable communication between sensors and effectors. The major informational systems of animals—nervous, hormonal, and immune—use chemical and electrical signals to process information.

sensory mechanisms The means by which internal or external stimuli are converted into neural signals.

effector mechanisms Adaptations that enable an organism to alter its physiological or behavioral state.

signaling mechanisms The means of transferring information between cells, organs, or organisms.

The concept of homeostasis also applies to the intracellular environment. Both unicellular and multicellular organisms must regulate the composition of their intracellular environments within a range that allows those cells to survive and function. Individual cells regulate these properties through actions of their membranes and, in the case of eukaryotes, their organelles. Thus self-regulation to maintain a more or less constant internal environment is a general attribute of all life.

Living organisms interact

Organisms do not live in isolation. Besides the internal hierarchy of the individual organism, there is also an external hierarchy of the biological world (**Figure 1.10B**). The populations of all the species that live and interact in a defined area are called a **community**. Communities together with their abiotic, or physical, environment constitute an **ecosystem**.

community A group of species living together at the same place and time.

ecosystem (eek' oh sis tum) The organisms of a particular community together with the physical and chemical environment in which they live.

Individuals in a population interact in many different ways. Animals eat plants and other animals and compete with other species for food and other resources. Some animals prevent other individuals of their own species from exploiting a resource, be it food, nesting sites, or mates. Animals may also cooperate with members of their own species, forming social units such as a termite colony or a flock of birds. Such interactions have resulted in the evolution of social behaviors such as communication and courtship displays.

Plants also interact with their external biotic and abiotic environment. Plants living on land depend on partnerships with fungi, bacteria, and animals. Some of these partnerships are necessary to obtain nutrients, some to produce fertile seeds, and still others to disperse seeds. Plants compete with each other for light and water and have ongoing evolutionary interactions with the animals that eat them. Through time, many adaptations such as thorns and toxins have evolved that protect plants from predation. Other adaptations such as flowers and fruits help attract the animals that assist in plant reproduction. The interactions of populations of plant and animal species in a community are major evolutionary forces that produce specialized adaptations.

The major ecosystems of Earth that cover broad geographic areas with distinguishing physical features and communities of organisms are known as [biomes](#). Examples of biomes include Arctic tundra, coral reefs, and tropical rainforests. All of the biomes on our planet make up the [biosphere](#). The ways in which species interact with one another and with their environment in populations, communities, and ecosystems is the subject of ecology, covered in [Part Ten](#) of this book. The preceding section outlined the major features of life—features that we will cover in depth in subsequent chapters of this book. Before going into the details of what we know about life, however, it is important to understand how scientists obtain information and how they use that information to broaden our understanding of life and to put that understanding to practical use.

biome (bye' ome) A major division of the ecological communities of Earth, characterized primarily by distinctive vegetation and the annual patterns of temperature and precipitation. A given biogeographic region contains many different biomes.

biosphere (bye' oh sphere) All regions of Earth (terrestrial and aquatic) and Earth's atmosphere in which organisms can live.

1.1 recap

All organisms are related by common descent from a single origin of life. They contain genetic information that encodes how they look and how they function. They also reproduce, extract energy from their environment, use energy to do biological work, synthesize complex molecules to build biological structures, regulate their internal environment, and interact with one another. Evolution has produced an enormous diversity of organisms that make up communities and ecosystems. Genomics helps scientists establish the evolutionary relationships between organisms.

learning outcomes

You should be able to:

- Explain how photosynthesis influenced the history of life on Earth.
 - Describe evidence that supports the common origin of all life on Earth.
 - Explain how natural selection can produce evolutionary change.
 - Explain how scientists classify organisms according to evolutionary relationships.
-

1. How were atmospheric oxygen levels related to the colonization of terrestrial environments?
 2. If we discovered life on another planet, how could we tell if it had a separate origin from life on Earth?
 3. Assume a population of fish becomes isolated in a dark cave environment, with no access to light from the surface. What major change might you expect in the population over time, and why?
 4. What information do biologists use to construct phylo-genetic trees?
-

***connect the concepts** The pathways that harvest chemical energy to do all the kinds of biological work necessary to support metabolism are presented in [Chapter 9](#).

***connect the concepts** How the structure of DNA codes for and is translated into proteins is discussed in Concept 4.1 and in more detail in [Chapters 13](#) and [14](#).

***connect the concepts** The story of Darwin's formulation of evolution by natural selection is covered in [Key Concept 20.1](#).

***connect the concepts** The regulation of body temperature is an important example of homeostasis that is discussed in [Chapter 39](#).

1.2 Biologists Investigate Life through Experiments That Test Hypotheses

Scientific investigations are based on observation, experimentation, data analysis, and logic. Scientists use many different tools and methods in making observations, collecting data, experimenting, analyzing data, and applying logic.

focus your learning

Scientific methods produce biological knowledge.

Observing and quantifying are important skills

Biologists observe the world around them. Our ability to observe has been greatly enhanced by technologies such as electron microscopes, rapid genome sequencing, magnetic resonance imaging, and global positioning satellites. These technologies allow us to observe everything from the distribution of molecules in the body to the movement of animals across continents and oceans.

Observation is a basic tool of biology, but as scientists we must be able to quantify the information, or [data](#), we collect and observe. Whether we are testing a new drug or mapping the migrations of whales, it is essential to apply mathematical and statistical methods to the data we collect. In our opening discussion of the responses of corals to temperature, it was essential for Rachael to measure temperatures accurately and to have a physical measure of bleaching so she could compare the responses of her corals to different conditions and conclude that the differences were more than just random variation.

data Quantified observations about a system under study.

Scientific methods combine observation, experimentation, and logic

Textbooks often describe “the scientific method,” as if there were a single, simple flow chart that all scientists follow. This is an oversimplification. Although flow charts such as the one shown in [Figure 1.12](#) incorporate much of what scientists do, you should not conclude that scientists necessarily progress through the steps of the process in one prescribed, linear order.

Figure 1.12 Scientific Methodology The process of observation, speculation, hypothesis, prediction, and experimentation is a cornerstone of modern science, although scientists may initiate their research at several different points. Answers gleaned through experimentation lead to new questions, more hypotheses, further

experiments, and expanding knowledge.

Observations lead to questions. To answer those questions, scientists make additional observations, formulate possible answers, and do experiments to test those possibilities. This investigative approach traditionally has five steps: (1) making observations; (2) asking questions; (3) forming hypotheses, which are tentative answers to the questions; (4) making predictions based on the hypotheses; and (5) testing the predictions by making additional observations or conducting experiments.

After posing a question, a scientist often uses **inductive logic** to propose a tentative answer. Inductive logic involves taking observations or facts and formulating a new proposition that is compatible with those observations or facts. Such a tentative proposition is a **hypothesis** (plural *hypotheses*). For example, in the opener to this chapter, you learned that Rachael Bay observed corals growing in pools that reached temperatures known to kill corals. She formulated two hypotheses:

- . The populations of corals in the warm pools have evolved genetic differences that enable them to survive heat stress (adaptations), or
- . Individual corals have the ability to adjust physiologically to different thermal conditions (acclimation).

inductive logic Involves making observations and then formulating one or more possible scenarios—hypotheses—that might explain those observations. (Contrast with deductive logic.)

hypothesis A tentative answer to a question, from which testable predictions can be generated. (Contrast with theory.)

Rachael and her colleagues conducted experiments and made observations to test these hypotheses. How do scientists design experiments to test hypotheses?

The next step in the scientific method is to apply a different form of logic—**deductive logic**—that starts with a statement believed to be true (the hypothesis) and then goes on to predict what facts would also have to be true to be compatible with that statement. Rachael's team tested their hypotheses by measuring how corals from the warm and cool pools responded to laboratory experiments that simulated the heat-stress conditions that occurred sometimes in the warm pools. They predicted that the cool-pool corals would bleach at higher rates under the experimental conditions than the warmpool corals would. That experiment revealed differences between the two populations, but did not reveal whether the differences were a result of long-term evolutionary changes in the populations (adaptations) or short-term acclimation of individuals to their current environments. The researchers therefore looked for genetic differences in the corals living in the warm and cool pools (adaptations). They also looked for differences in gene expression patterns when the corals were transplanted to different environments (acclimation). Did the two populations have fundamental genetic differences, or did the environments they lived in stimulate different patterns of gene expression and therefore physiological acclimation?

deductive logic Logical thought process that starts with a premise believed to be true then predicts what facts would also have to be true to be compatible with that premise. (Contrast with inductive logic.)

Good experiments have the potential to falsify hypotheses

Once predictions are made from a hypothesis, experiments can be designed to test those predictions. The most informative experiments are those that have the ability to show that the prediction is wrong. If the prediction is wrong, the hypothesis must be questioned, modified, or rejected.

There are two general types of experiments, both of which compare data from different groups or samples:

- **Controlled experiments** manipulate one factor of interest while holding other variables constant as a means of testing the influence of the manipulated variable.
- **Comparative experiments** compare data gathered from different populations that differ in multiple, unknown ways.

controlled experiment An experiment in which a sample is divided into groups whereby experimental groups are exposed to manipulations of an independent variable while one group serves as an untreated control. The data from the various groups are then compared to see if there are changes in a dependent variable as a result of the experimental manipulation. (Contrast with comparative experiment.)

comparative experiment Experimental design in which data from various unmanipulated samples or populations are compared, but in which variables are not controlled or even necessarily identified. (Contrast with controlled experiment.)

Rachael Bay and her colleagues conducted both types of experiments, to reveal genetic differences between the coral populations as well as their abilities to acclimate to different temperature environments.

In a controlled experiment, we predict on the basis of our hypothesis that some critical factor, or variable, has an effect on the phenomenon we are investigating. We devise some method to manipulate *only that variable* in an “experimental” group and compare the resulting data with data from an unmanipulated “control” group. If the predicted difference occurs, we then apply statistical tests to ascertain the probability that the manipulation caused the difference (as opposed to the difference being the result of random chance). **Investigating Life: Corals in Hot Water** describes a controlled experiment examining the effect of pool of origin on the response of corals to heat stress done by Rachael Bay and other members of the Palumbi laboratory. A good controlled experiment is not easy to design because biological variables are so interrelated that it is sometimes difficult to alter just one. In this experiment, the controlled variable was whether the experimental corals came from the cool-pool or the warm-pool environment. They were then subjected to the same thermal stresses and their responses measured as extent of bleaching. The control groups were corals not exposed to the thermal stress protocol.

A comparative experiment starts with the prediction that there will be a difference between samples or groups based on the hypothesis. Unlike in a controlled experiment, we cannot control all the variables in a comparative experiment; often we cannot even identify all the variables involved. We are simply gathering and comparing data from different sample groups. Rachael and her colleagues did a comparative experiment in addition to the controlled experiment shown in *Investigating Life: Corals in Hot Water*. They analyzed and compared the genetic makeup of corals taken from the warm and cool pools.

Statistical methods are essential scientific tools

Whether we do comparative or controlled experiments, we have to decide whether there is a real difference between the samples, individuals, groups, or populations in the study. How do we

decide whether a measured difference is enough to support or falsify a hypothesis? In other words, how do we decide in an unbiased, objective way that the measured difference is significant?

Significance is measured with statistical methods. Random variation is almost always present in any set of measurements. Statistical tests calculate the probability that the differences observed in an experiment could be due to random variation. The results of statistical tests are therefore probabilities. A statistical test starts with a **null hypothesis**—the premise that observed differences are the result of random variation that arises from drawing two finite samples from the same population. When quantified observations, or data, are collected, statistical methods are applied to those data to see if there is sufficient evidence to reject the null hypothesis.

null hypothesis In statistics, the premise that any differences observed in an experiment are simply the result of random differences that arise from drawing two finite samples from the same population.

Corals in Hot Water

experiment

Original Paper: Palumbi, S. R., D. J. Barshis, N. Traylor-Knowles and R. A. Bay. 2014. Mechanisms of reef coral resistance to future climate change. *Science* 344: 895–898.

Rachael Bay and her colleagues did a controlled experiment by bringing corals from the warm and the cool tidal pools into the laboratory and then subjecting them to cycles of heat stress that simulated the conditions that sometimes occurred in the warm tidal pools. The outcome measure was bleaching—the loss of photosynthetic symbionts (dinoflagellates) from the coral bodies.

HYPOTHESIS ► Heat stress results in coral bleaching, but corals from warm pools are less subject to bleaching under heat stress than are corals from cool pools.

METHOD

1. Transplant corals from warm and cool pools into laboratory aquaria maintained at a safe temperature.
2. Subject experimental corals to heat stress (the experimental condition) by simulating the daily temperature cycle in the warm pools.
3. Measure coral bleaching (the dependent variable) as the ratio of chlorophyll (the photosynthetic pigment of the symbionts) in the corals exposed to heat stress versus in the controls in non-stressed conditions. A ratio of less than 1.0 indicates higher bleaching in the heat-stressed corals than in the controls.

RESULTS Corals from both cool pools and warm pools exhibited higher bleaching under heat stress than controls did, but the cool-pool corals showed higher average levels of bleaching than the warm-pool corals did. (You will calculate the statistical significance of this difference in the following work with the data exercise.)

CONCLUSION ► The warm-pool corals showed lower effects of heat stress than the cool-pool corals did, although both populations showed increased bleaching under heat stress. The difference in the populations could be explained either by genetic adaptation to heat stress in the populations of warm-pool corals or by physiological acclimatization of individuals exposed to warm-pool conditions, or by some combination of the two.

work with the data

The bar graph in the Results section of the experiment shows that both cool-pool corals and warm-pool corals showed increased levels of bleaching under heat stress, relative to controls. It also shows that the cool-pool corals showed greater relative bleaching under heat stress than did the warm-pool corals. But how do we know that these differences are greater than would be expected if the variation within and between samples represents nothing more than random variation? Here we will use some simple tests to see if the differences measured are significant (unlikely due to random variation).

Average chlorophyll ratio	Cool-pool corals	Warm-pool corals
0.0	0	0
0.1	0	0
0.2	1	0
0.3	1	0
0.4	4	0
0.5	7	0
0.6	1	0
0.7	1	1
0.8	2	3
0.9	0	3
1.0	0	1

QUESTIONS ►

1. Prepare a bar graph based on these data. Display the chlorophyll ratios on the x axis, and show the number of corals that exhibited each ratio on the y axis.
2. First, let's consider if there is a significant effect of heat stress in each of the two groups. At the outset we assume that there is no effect of heat stress in either group—this is called our null hypothesis (H_0). We use statistical tests to decide if we can reject the null hypothesis and conclude that there *is* an effect of heat stress. If the null hypothesis is true, then we would expect that any differences in chlorophyll levels between control and experimental populations are due to random variation, and so we would expect the chlorophyll ratios to be greater than 1.0 as often as they are less than 1.0. In other words, the expected distribution of values < 1 and > 1 is like the expected distribution of heads and tails in a coin toss. Let's first consider the cool-pool corals. There are 17 samples, and all 17 had chlorophyll ratios < 1.0 . The probability of this happening at random is the same as getting 17 heads in 17 flips of a fair coin (by a "fair coin" we mean the probability of heads in one flip = 0.5). Using this criterion, calculate the probability of the null hypothesis (H_0 : no effect of heat stress on bleaching) for each of the two populations.
3. Now let's consider if there is a significant difference in the level of bleaching in the cool-pool versus the warm-pool corals. Our null hypothesis in this case is that the levels of bleaching are the same in both groups. If the null hypothesis is true, then we would expect (on average) the same distribution of chlorophyll ratios in the samples of both groups. From the Results section in the experiment, we see that the average chlorophyll ratio observed in the cool-pool samples is 0.5, and the average chlorophyll ratio observed in the warm-pool samples is 0.85. Would we expect a difference this great if the distributions of the two samples were drawn from the same underlying distribution of values? To find out, write each of the 25 observed chlorophyll ratios (from both groups) on an index card. Thoroughly mix and shuffle the cards to randomize their order, and then deal them into two groups of the same size as the cool-pool samples (17) and warm-pool samples (8). Calculate the average ratios in these randomized samples. Repeat this procedure or combine the results of your randomization test with those of other students in your class. How often do you see a difference as great as the observed difference in the two samples (0.85–0.5, or a difference of 0.35)?
4. What do these results suggest about the possible response of coral populations in different environments to ocean warming?

A similar **work with the data** exercise may be assigned in LaunchPad.

More specifically, statistical methods tell us the probability of obtaining the same results by chance even if the null hypothesis were true. *We need to eliminate, insofar as possible, the chance that any differences showing up in the data are merely the result of random variation in the samples tested.* Scientists generally conclude that the differences they measure are significant if statistical tests show that the probability of error (that is, the probability that a difference as large as the one observed could be obtained by mere chance) is 5 percent or lower. They often use more stringent criteria for rejecting the null hypothesis, however, depending on the consequences of accepting a wrong hypothesis. [Appendix B](#) of this book offers a short primer on statistical methods to which you can refer as you analyze data that will be presented throughout the text.

Discoveries in biology can be generalized

All life is related by descent from a common ancestor, shares a genetic code, and consists of similar biochemical building blocks. Therefore knowledge gained from investigations of one type of organism can, with thought and care, be generalized to other organisms. Biologists use **model systems** for research, knowing that they can extend their findings from such systems to other organisms. For example, our basic understanding of the chemical reactions in cells came from research on bacteria but is applicable to all cells, including those of humans. Similarly, the biochemistry of photosynthesis—the process by which all green plants use sunlight to produce biological molecules—was worked out largely from experiments on *Chlorella*, a unicellular green alga. Much of what we know about the genes that control plant development is the result of work on *Arabidopsis thaliana*, a relative of the mustard plant. Knowledge about how animals, including humans, develop has come from work on sea urchins, frogs, chickens, roundworms, mice, and fruit flies. Being able to generalize from model systems is a powerful tool in biology.

Not all forms of inquiry are scientific

Science is a unique human endeavor that has certain standards of practice. Other areas of scholarship share with science the practice of making observations and asking questions, but scientists are distinguished by what they do with their observations, how they frame their questions, and how they determine their answers. Quantifiable data, subjected to appropriate statistical analysis, are critical in evaluating hypotheses. The Investigating Life boxes and the Work with the Data exercises you will find throughout this book are intended to reinforce this way of thinking. *Scientific observation, hypothesis generation, and experimental testing constitute the most powerful approach humans have devised for learning about the world and how it works.*

Scientific explanations for natural processes are objective and reliable because *a hypothesis must be testable* and *a hypothesis must have the potential of being rejected* by direct observations and experiments. Scientists must clearly describe the methods they use to test hypotheses so that other scientists can repeat their results. Not all experiments are repeated, but surprising or controversial results are always subjected to independent verification. Scientists worldwide share this process of testing and rejecting hypotheses, contributing to a common body of scientific knowledge.

If you understand the methods of science, you can distinguish science from non-science. Art, music, and literature all contribute to the quality of human life, but they are not science. They do not use scientific methods to establish what is fact. Religion is not science, although religions have historically attempted to explain natural events ranging from unusual weather patterns to crop failures to human diseases. Most such phenomena that at one time were mysterious can now be explained in terms of scientific principles. Fundamental tenets of religious faith, such as the existence of a supreme deity or deities, cannot be confirmed or refuted by experimentation

and are thus outside the realm of science.

The power of science derives from strict objectivity and absolute dependence on evidence based on *reproducible and quantifiable observations*. A religious or spiritual explanation of a natural phenomenon may be coherent and satisfying for the person holding that view, but it is not testable and therefore it is not science. To invoke a supernatural explanation (such as a “creator” or “intelligent designer” with no known bounds) is to depart from the world of science. Science does not necessarily say that religious beliefs are wrong; they are simply not part of the world of science and are untestable using scientific methods.

Science describes how the world works. It is silent on the question of how the world “ought to be.” Many scientific advances that contribute to human welfare also raise major ethical issues. Recent developments in genetics and developmental biology may enable us to select the sex of our children, to use stem cells to repair our bodies, and to modify the human genome. Although scientific knowledge may enable us to do these things, science cannot tell us whether or not we *should* do so, or if we choose to do them, how we should regulate them. Such issues are as crucial to human society as the science itself, and a responsible scientist does not lose sight of these questions or neglect the contributions of the humanities and social sciences in attempting to come to grips with them.

1.2 recap

Scientific methods of inquiry start with the formulation of hypotheses based on observations and data. Comparative and controlled experiments are carried out to test hypotheses. Statistics are essential for drawing conclusions from the data obtained in experiments. Because organisms can be compared through their evolutionary relationships, the results of experiments can frequently be generalized to apply to other species.

learning outcomes

You should be able to:

- Explain the roles of inductive logic and deductive logic in scientific inquiry.
- Describe how a controlled experiment is designed.
- Differentiate between controlled experiments and comparative experiments.
- Explain why model organisms are used in biological research.

1. What is the relationship between a hypothesis and an experiment?
2. What is controlled in a controlled experiment?
3. What features characterize questions that can be answered using a comparative approach rather than through a controlled experiment?
4. Why is it often possible to generalize the results of biological research on one species to very different species?

The vast body of scientific knowledge accumulated over centuries of human civilization allows us to understand and manipulate aspects of the natural world in ways that no other species can. These abilities present us with challenges, opportunities, and above all, responsibilities.

1.3 Understanding Biology Is Important for Health, Well-Being, and Public-Policy Decisions

Human beings exist in and depend on a world of living organisms. The oxygen we breathe is produced by the photosynthetic activity of countless billions of individual organisms. The food that fuels our bodies comes from the tissues of other living organisms. The fuels that power our cars, trucks, and planes are carbon molecules produced by living organisms—mostly millions of years ago. Inside and out, our bodies are covered in complex communities of living unicellular organisms. Some help us be healthy, but others can invade our bodies and cause mild to serious diseases, or even death. These interactions with other species are not limited to humans. Ecosystems depend on thousands of complex interactions among the millions of species that inhabit Earth. Understanding biological principles is essential for us to lead healthy productive lives and to be good stewards of our planet.

focus your learning

Biology contributes many things to society.

Modern agriculture depends on biology

Agriculture represents some of the earliest human applications of biological principles. Beginning about 10,000 years ago, humans began to cultivate and harvest grains. It is probable that even in those early times farmers selected the most productive or otherwise favorable plants and animals to use as seed stock for propagation, and over generations farmers continued and refined these practices. By 1960, the worldwide yield of food grains reached a billion tons, but human population growth outpaced agricultural productivity and starvation was common in developing countries. Catastrophic famine was predicted for the 1970s. In response to those predictions, developed countries initiated huge efforts to produce genetically improved, higher-yielding food grain varieties. These highly successful research programs resulted in what has been called the Green Revolution, and by the year 2000 the worldwide yield of food grains, which make up about 50 percent of the calories in the human diet, reached 2 billion tons. Increasing knowledge of plant and animal biology has transformed agriculture in many ways and has resulted in huge boosts in food production.

A new threat to agriculture and the world food supply is global climate change. Some regions are becoming wetter and others drier, and those changes affect traditional agricultures. An example is rice, which normally grows in shallow water in rice paddies ([Figure 1.13](#)). But, common rice varieties cannot survive complete submergence for more than a few days, and are therefore killed by flooding caused by too much rain. In India and Bangladesh alone, annual flooding can destroy about 4 million tons of rice, enough to feed 30 million people. In recent years plant geneticists Pam Ronald, David Mackill, and their colleagues at the University of California at Davis have discovered a single gene from an ancient variety of rice that when genetically engineered into the current rice varieties makes them capable of surviving total submergence for many days. Advances such as this may help save the benefits of the Green Revolution from the new problems generated by global climate change.

Figure 1.13 A Green Revolution Advances in agricultural plant genetics have vastly increased yields and nutritional value of crops such as the food grains that make up about 50 percent of calories in the human diet. New molecular genetic technologies make even greater advances possible. The strains of rice on the right have been modified to increase resistance to prolonged flooding; the rice plants on the left are unmodified, and have died from over-exposure to flood conditions.

Over the past few decades, detailed knowledge of the genomes of many domestic species and the development of technology for directly recombining genes have allowed biologists to develop new breeds and strains of animals, plants, and fungi of agricultural interest. New strains of crop plants are being developed that are resistant to pests or tolerant of drought or, in the case of rice, flooding. Moreover, understanding evolutionary theory allows biologists to devise strategies for the application of pesticides that minimize the evolution of pest resistance. And better understanding of plant–fungus relationships results in better plant health and higher productivity. These are just a few of the many ways that biology continues to inform and improve agricultural practice.

Biology is the basis of medical practice

People have speculated about the causes of diseases and searched for methods to combat them since ancient times. Long before the microbial causes of many diseases were known, people recognized that infections could be passed from one person to another, and the isolation of infected persons has been practiced as long as written records have been available.

Modern biological research informs us about how living organisms work, and about why they develop the problems and infections that we call disease. In addition to diseases caused by infectious organisms, we now know that many diseases are genetic—meaning that variants of genes in our genomes cause particular problems in the way we function. Developing appropriate treatments or cures for diseases depends on understanding the origin, basis, and effects of these diseases, as well as understanding the consequences of any changes we make. For

example, the recent resurgence of tuberculosis is the result of the evolution of bacteria that are resistant to antibiotics. Dealing with future tuberculosis epidemics will require understanding aspects of molecular biology, physiology, microbial ecology, and evolution—in other words, many of the general principles of modern biology.

Many of the microbial organisms that are periodically epidemic in human populations have short generation times and high mutation rates. For example, we need yearly vaccines for flu because of the high rate of evolution of influenza viruses, the causative agent of flu. Evolutionary principles help us understand how influenza viruses are changing, and can even help us predict which strains of influenza virus are likely to lead to future flu epidemics. This medical understanding—which combines an application of molecular biology, evolutionary theory, and basic principles of ecology—allows medical researchers to develop effective vaccines and other strategies for the control of major epidemics ([Figure 1.14](#)).

Figure 1.14 Medical Applications of Biology Improve Human Health Vaccination to prevent disease is a biologically based medical practice that began in the eighteenth century. Today evolutionary biology and genomics provide the basis for constant updates to vaccines that protect humans from virusborne diseases such as flu and measles. In the developed world, vaccinations are so commonplace that some are offered on a “drive-through” basis.

Biology can inform public policy

Thanks to the deciphering of genomes and our newfound ability to manipulate them, vast new possibilities now exist for controlling human diseases and increasing agricultural productivity—but these capabilities raise ethical and policy issues. How much and in what ways should we tinker with the genes of humans and other species? Does it matter whether the genomes of our crop plants and domesticated animals are changed by traditional methods of controlled breeding or by the biotechnology of gene transfer? What rules should govern the release of genetically modified organisms into the environment? Science alone cannot provide all the answers, but wise policy decisions must be based on accurate scientific information.

Biologists are increasingly called on to advise government agencies concerning the laws, rules, and regulations by which society deals with the increasing number of challenges that have a biological basis. As an example of the value of scientific knowledge for the assessment and formulation of public policy, consider a management problem. Scientists and fishermen have long known that Atlantic bluefin tuna (*Thunnus thynnus*) have a western breeding ground in the

Gulf of Mexico and an eastern breeding ground in the Mediterranean Sea ([Figure 1.15](#)). Overfishing led to declining numbers of bluefin tuna, especially in the western-breeding populations, to the point of these populations being endangered.

Figure 1.15 Bluefin Tuna Do Not Recognize Boundaries (A) Marine biologist Barbara Block attaches computerized data-recording tracking tags to a live bluefin tuna before returning it to the Atlantic Ocean, where its travels will be monitored. (B) Tracking data from eastern (Mediterranean) and western (Gulf of Mexico) breeding populations of bluefin tuna. At one time commercial fishing regulatory agencies assumed that bluefins from western- and eastern-breeding populations fed on their respective sides of the Atlantic. To speed recovery of the endangered western population, fishing quotas were created for each side of the mid-Atlantic Ocean (dashed line).

Q: Based on Dr. Block's data, does it seem likely that fishing quotas based on the mid-Atlantic boundary line would protect the western-breeding population of bluefin tuna?

Initially it was assumed by scientists, fishermen, and policy makers alike that the eastern and western populations had geographically separate feeding grounds as well as separate breeding grounds. Acting on this assumption, an international commission drew a line down the middle of the Atlantic Ocean and established strict fishing quotas on the western side of the line, with the intent of allowing the western population to recover. Modern tracking data, however, revealed that in fact the eastern and western bluefin populations mix freely on their feeding grounds across the entire North Atlantic—a swath of ocean that includes the most heavily fished waters in the world. Tuna caught on the eastern side of the line could just as likely be from the western-breeding population as the eastern; thus the established policy could not achieve its intended goal.

Scientific knowledge can make significant contributions to the formulation of wise public

policy, but economic and political factors frequently outweigh scientific recommendations. It is particularly lamentable when solid scientific evidence is discounted or ignored because it is inconvenient. An example is the rejection by many policy makers of strong evidence for and scientific consensus on global climate change.

Biology is crucial for understanding ecosystems

Earth has been changing since its formation and continues to change. Human activity, however, is resulting in an unprecedented *rate* of change in the world's ecosystems. For example, the mining and consumption of fossil fuels is releasing massive quantities of carbon dioxide into Earth's atmosphere. This anthropogenic (human-generated) increase in atmospheric carbon dioxide is largely responsible for the rapid rate of global climate warming recorded over the last 50 years (**Figure 1.16**).

(A) 1941

(B) 2004

Figure 1.16 A Warmer World Earth's climate has been steadily warming for the last 150 years. The rate of this warming trend has also steadily increased, resulting in the rapid melting of polar ice caps, glaciers, and alpine (mountaintop) snow and ice. **(A, B)** These photographs shows the effects of 63 years of climate change on two ancient, longstanding glaciers in Alaska. Over that time, Muir Glacier retreated some 7 kilometers and can no longer be seen from the original vantage point. Understanding how biological populations respond to such change requires integration of biological principles from molecular biology to ecosystem ecology.

Our use of natural resources is putting stress on the ability of Earth's ecosystems to continue to produce the goods and services on which our society depends. Human activities are changing global climates at an unprecedented rate and are leading to the extinctions of large numbers of species (such as the reef-building corals featured in this chapter). The modern, warmer world is also experiencing the spread of new diseases and the resurgence of old ones. Biological knowledge is vital for determining the causes of these changes and for devising policies to deal with them.

Biodiversity helps us understand, enjoy, and appreciate our world

Beyond issues of policy and pragmatism lies the human "need to know." Most people are fascinated by the richness and diversity of life and want to know more about organisms, how they function, and how they interact ([Figure 1.17](#)). For the biologist, biodiversity offers an inexhaustible source of new questions and opportunities for new investigations and experiments. New discoveries and greater knowledge generate questions no one thought to ask before. Science is a never-ending quest.

Figure 1.17 Exploring Life on Earth These biologists are collecting insects in the top boughs of a spruce tree in the Carmanah Valley of Vancouver, Canada. Biologists estimate that the number of species discovered to date is only a small percentage of the species that inhabit Earth. To fill this gap in our knowledge, biologists around the world are applying thorough sampling techniques and new genetic tools to document and understand the Earth's biodiversity.

Apart from scientific endeavors, biodiversity enriches our lives. You may be an avid birdwatcher, or enjoy gardening, or seek out particular species if you hunt or fish. Some people observe or collect butterflies, or mushrooms, or other groups of plants and animals. Displays of spring wildflowers bring out throngs of human viewers. Hiking and camping in natural areas full of diverse species are activities enjoyed by millions. Learning about biology greatly increases our enjoyment of the world around us.

1.3 recap

Biology informs us about the structure, processes, and interactions of the living organisms that make up our world. Informed decisions about food and energy production, health, and our environment depend on biological knowledge. Biology also addresses the human need to understand the world around us, and helps us appreciate the diverse planet we call

home.

learning outcomes

You should be able to:

- Explain the relevance of biology to people's daily lives.
- Apply biological knowledge to answer a question that pertains to everyday life.

1. Describe an example of how modern biology is applied to agriculture.
2. Discuss an example of a biological problem that is directly related to global climate change.
3. Why are some antibiotics no longer as effective for treating bacterial diseases as they were when these drugs were introduced?

This chapter has provided a brief roadmap of the rest of the book. Thinking about the principles outlined here may help you clarify and make sense of the pages of detailed description to come.

QA How might experiments on heat stress in corals be used to predict the response of corals to global warming?

How can we put studies like the one conducted by Rachael and her colleagues to use? One way is to use the information to make predictions. As we've noted in this chapter, abundant evidence shows that Earth's climate is warming as a result of increased levels of CO₂ in our atmosphere. Can corals survive this global warming, or will they all lose their photosynthetic dinoflagellates and die? The experiments and observations done by Rachael's team suggest that higher temperatures will lead to increased coral bleaching, but that some short-term acclimation of individuals can occur. If global warming is slowed sufficiently, longer-term processes of evolution will act on the surviving corals that have genetic adaptations that increase their tolerance to warmer waters. This selection process should result in genetic changes in populations, which will allow more corals to survive. How well acclimation and adaptation can work to ensure the survival of corals depends on many factors, including the average life span of individual corals, the rate of global warming, and the availability of alternative heat-resistant dinoflagellates. The basic research conducted by Rachael's team is a first, but critical, step in predicting the future response of corals to global warming.

Future directions

As described, the corals in Rachael's study have certain species of dinoflagellates growing within their cells. The corals provide a suitable environment for the dinoflagellates and the dinoflagellates provide nutrients for the corals. Such a mutually beneficial relationship is called symbiosis. The bleaching response to high temperature implies dysfunction in the dinoflagellates, leading to their expulsion from the corals. Understanding thermal tolerance of the corals therefore requires greater understanding of genetic changes and acclimation of the symbiotic dinoflagellates. Other studies have shown that some corals contain multiple strains of dinoflagellates, and these strains change in abundance when the corals are grown at different temperatures, perhaps contributing to thermal tolerance. There are many species and strains of dinoflagellates, but coral species usually are associated with specific species. Future research could focus on thermal tolerance of dinoflagellates to identify genes that confer thermal tolerance. Additional research could be to find ways of transferring those genes into other species of dinoflagellates or to find ways of infecting corals endangered by rising temperatures with strains of temperature-tolerant symbionts.

► 1.1 Living Organisms Share Similarities and a Common Origin

- **Biology** is the scientific study of organisms, including their characteristics, evolution, functions, and interactions.

biology [Gk. *bios*: life + *logos*: study] The scientific study of living things.

- All living organisms are related to one another through common descent. Shared features among organisms support the concept of a common ancestry for all life on Earth. These features include: a common set of chemical building blocks, a nearly universal genetic code, sequence similarities across fundamental genes, and similarities in cellular structure and function.
- Cells evolved early in the history of life. **Cellular specialization** allowed multicellular organisms to increase in size and diversity. **Review Figure 1.2**

cellular specialization In multicellular organisms, the division of labor such that different cell types become responsible for different functions (e.g., reproduction or digestion) within the organism.

- **Photosynthesis** provided a means of capturing energy directly from sunlight, and over time changed Earth's atmosphere.

photosynthesis (foe tow sin' the sis) [Gk. creating from light] Metabolic processes carried out by green plants and some microorganisms by which visible light is trapped and the energy used to synthesize compounds such as ATP and glucose.

- The instructions for a cell are contained in its **genome**, which consists of **DNA** molecules made up of sequences of **nucleotides**. Specific segments of **DNA** called **genes** contain the information the cell uses to make proteins through processes of transcription and translation. **Review Figure 1.6**

genome (jee' nome) The complete DNA sequence for a particular organism or individual.

DNA (deoxyribonucleic acid) The fundamental hereditary material of all living organisms. In eukaryotes, stored primarily in the cell nucleus. A nucleic acid using deoxyribose rather than ribose.

nucleotide The basic chemical unit in nucleic acids, consisting of a pentose sugar, a phosphate group, and a nitrogen-containing base.

DNA (deoxyribonucleic acid) The fundamental hereditary material of all living organisms. In eukaryotes, stored primarily in the cell nucleus. A nucleic acid using deoxyribose rather than ribose.

gene [Gk. *genes*: to produce] A unit of heredity. Used here as the unit of genetic function which carries the information for a polypeptide or RNA.

- **Evolution**—change in the genetic makeup of biological **populations** through time—is a fundamental principle of life. Populations evolve by means of several different processes, including **natural selection**, which is responsible for the diversity of **adaptations** found in living organisms.

evolution Any gradual change. Most often refers to organic or Darwinian evolution, which is the genetic and resulting phenotypic change in populations of organisms from generation to generation. (See macroevolution, microevolution. Contrast with speciation.)

population (1) In biology, any group of organisms coexisting at the same time and in the same place and capable of interbreeding with one another. (2) In statistics, a study group of interest.

natural selection The differential contribution of offspring to the next generation by various genetic types belonging to the same population. The mechanism of evolution proposed by Charles Darwin.

adaptation (a dap tay' shun) (1) In evolutionary biology, a particular structure, physiological process, or behavior that makes an organism better able to survive and reproduce. Also, the evolutionary process that leads to the development or persistence of such a trait. (2) In sensory neurophysiology, a sensory cell's loss of sensitivity as a result of repeated stimulation.

- Biologists use fossils, anatomical similarities and differences, and molecular comparisons of genomes to reconstruct the history of life. Life is divided into two major lineages—**Bacteria**, **Archaea**. One lineage of Archaea became specialized as **Eukarya**, which includes all multicellular organisms. **Review Figure 1.9**
- Life can be studied at different levels of organization within a biological hierarchy. The specialized cells of multicellular organisms are organized into **tissues**, **organs**, and **organ systems**.

tissue A group of similar cells organized into a functional unit; usually integrated with other tissues to form part of an organ.

organ [Gk. *organon*: tool] A body part, such as the heart, liver, brain, root, or leaf. Organs are composed of different tissues integrated to perform a distinct function. Organs, in turn, are integrated into organ systems.

organ system An interrelated and integrated group of tissues and organs that work together in a physiological function.

- Living organisms, whether unicellular or multicellular, must regulate their internal environment to maintain **homeostasis**, the range of physical conditions necessary for their survival and function.

homeostasis (home' ee o sta' sis) [Gk. *homos*: same + *stasis*: position] The maintenance of a steady state, such as a constant temperature, by means of physiological or behavioral feedback responses.

- Individual organisms form populations and interact with other organisms of their own and other species. The populations that live and interact in a defined area form a **community**, and communities together with their abiotic (nonliving) environment constitute an **ecosystem**. **Review Figure 1.10**, **Activity 1.1**

ecosystem (eek' oh sis tum) The organisms of a particular community together with the physical and chemical environment in which they live.

▶ 1.2 Biologists Investigate Life through Experiments That Test Hypotheses

- Scientific methods combine observation, the gathering of information (data), experimentation, and the application of logic to study the natural world. Many scientific investigations involve five steps: making observations, asking questions, forming hypotheses, making predictions, and testing those predictions. **Review Figure 1.12**
- **Hypotheses** are tentative explanations of observations or answers to questions. Predictions made on the basis of a hypothesis are tested with additional observations and experiments. The two general types of experiments are **comparative** and **controlled**. **Review Investigating Life: Corals in Hot Water, Animation 1.1**
- Quantifiable data are critical in evaluating hypotheses. Statistical methods are applied to quantitative data to establish whether the differences observed could be the result of chance. These methods start with the null **hypothesis** that there are no differences apart from random variation. **See Appendix B**

hypothesis A tentative answer to a question, from which testable predictions can be generated. (Contrast with theory.)

- Biological knowledge obtained from a **model system** may be generalized to other species.

▶ 1.3 Understanding Biology Is Important for Health, Well-Being, and Public-Policy Decisions

- Application of biological knowledge is responsible for vastly increased agricultural production.
- Understanding and treating human disease requires integrating a wide range of biological principles, from molecular biology to cell biology, physiology, evolution, and ecology.
- Biologists are often called on to advise government agencies on the solutions to important problems that have a biological component.
- Biology is increasingly important for understanding how organisms interact in a rapidly changing world.
- Biology helps us understand, appreciate, and enjoy the diverse living world.

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify your understanding of this chapter. **LearningCurve** adapts to your responses, giving you the practice you need to master each key concept.

► Apply What You've Learned

Review

- .1 Living organisms have influenced the history of the planet Earth.
- .1 Major characteristics are shared among all living things.
- .1 Biological populations change over time.
- .2 Scientific methods produce biological knowledge.
- .3 Biology contributes many things to society.

Original Paper: Lindsey, H. A., J. Gallie, S. Taylor, and B. Kerr. 2013. Evolutionary rescue from extinction is contingent on a lower rate of environmental change. *Nature* 494: 463–467.

As many as half of the antibiotics that are used in human medicine may be incorrectly prescribed or completely unnecessary. Antibiotics are also given to food animals in an effort to prevent disease. A general overuse of these drugs has contributed to a significant increase in drug-resistant pathogens. If you were raising animals for food, what evidence could you use to decide if it is better to treat the animals routinely with a low dose of antibiotics or wait until symptoms occur and then administer a high dose?

Researchers used serial transfer to propagate 1,255 populations of the bacterium *Escherichia coli* in an environment in which concentrations of the antibiotic rifampicin were increased over time. Each population began in liquid medium containing no antibiotic and ended at the same maximum concentration of rifampicin.

During the serial transfers, populations received one of three treatments. Populations designated as “Sudden” were exposed to the maximum rifampicin concentration immediately after their first transfer and continued to receive this maximum concentration in each subsequent transfer. Populations designated as “Moderate” were exposed to moderately increasing concentrations of rifampicin; the maximum concentration of rifampicin was reached halfway through the transfers. Populations designated as “Gradual” were exposed to more gradual increases of rifampicin; the maximum concentration of rifampicin was reached at the very end of the transfers.

!!**Figure A** summarizes the treatment conditions and **Figure B** shows the percentage of populations in each treatment that survived the experiment. The number above each bar shows how many of the initial 1,255 populations underwent each type of treatment.

Figure A

Figure B

Questions

1. What do the results of this investigation show about the effects of sudden versus gradual environmental changes on the evolution of biological populations? Explain how these results help explain extinctions and adaptations of populations in changing environments.
2. In what ways does this investigation model events that shaped the history of life on Earth?
3. Explain what makes it reasonable for us to infer that similar results would be observed if this investigation were repeated using a plant, insect, or mammal population in a changing environment.
4. Identify this investigation as either a comparative or a controlled study. Design an experiment of the other type of study that tests the hypothesis that organisms can develop adaptations to changing surroundings. Explain your reasoning.
5. Suppose a research organization has requested funding for longterm research to develop a continuous pipeline of new antibiotics over the next 50 years. Could the organization use results from this investigation to support their request? Explain.

[2.2 Atoms Bond to Form Molecules](#)

[2.3 Atoms Change Partners in Chemical Reactions](#)

[2.4 Water Is Critical for Life](#)

Tracking a Dinosaur

“You are what you eat—and that applies to teeth” is a modification of a famous saying about body chemistry. One of the important atoms in organisms is oxygen (O), which is part of water (H₂O). Oxygen has two naturally occurring variants called isotopes; they have the same chemical properties but different weights because their nuclei have different numbers of neutrons. Both isotopes of O are incorporated into the bodies of animals that consume the isotopes in water and food.

The hard surface of teeth, called enamel, is made up largely of calcium phosphate, which contains oxygen atoms. The iso-topic composition of the oxygen in enamel varies depending on where an animal was living when the enamel was made. When water evaporates from the ocean, it forms clouds that move inland and release rain. Water with the heavier isotope of O is heavier, and tends to fall more readily than water containing the lighter isotope. As a result, regions of the world that are closer to the ocean receive rain containing more heavy water than do regions farther away, and these differences are reflected in the bodies of animals that dwell in these regions.

This property has been used to reveal an astounding fact about dinosaurs that lived in the great basins of southwestern North America about 150 million years ago.

Camarasaurus was big—up to 25 meters long and weighing up to 45 metric tons. Henry Ficke from Colorado College analyzed the oxygen isotopes in the enamel of *Camarasaurus* fossils and found two kinds of teeth: Some had the heavy oxygen content typical of rains and rocks in the basin region. But others, surprisingly, had a lower proportion of heavy oxygen, indicating that these animals had lived at higher elevations 300 km to the west. This indicated for the first time that dinosaurs migrated a long way from west to east. The reason for this migration is not clear. *Camarasaurus* ate a plant-based diet, and perhaps the migration was directed at finding food.

Many biological phenomena are analyzed and understood in the context of chemistry. You will learn, for example, that adding even one atom to a large molecule can change its character and function. Analyzing the isotopes in dinosaur teeth is but one example of how chemical analysis has led to advances in biological science.

QA What insights into biological systems have been discovered through isotope analysis?

2.1 Atomic Structure Explains the Properties of Matter

All matter is composed of [atoms](#). Atoms are tiny—more than a trillion (10^{12}) of them could make up the period at the end of this sentence. Atoms and their component particles have volume and mass, which are characteristics of all matter. [Mass](#) is a measure of the quantity of matter present; the greater the mass, the greater the quantity of matter. Atoms also have electric charges.

atom [Gk. *atomos*: indivisible] The smallest unit of a chemical element. Consists of a nucleus and one or more electrons.

mass A measure of the quantity of matter present; the greater the mass, the greater the quantity of matter.

focus your learning

Six elements (carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulfur) make up most of the matter found in living organisms.

Reactive atoms tend to gain or lose electrons from their valence (outer) shell in order to achieve a full valence shell, because a full valence shell confers stability.

The structure of an atom determines its properties.

What are atoms?

Each atom consists of a dense, positively charged [nucleus](#), around which one or more negatively charged [electrons](#) move ([Figure 2.1](#)). The nucleus contains one or more positively charged [protons](#) and may contain one or more [neutrons](#) with no electric charge.

nucleus (new' klee us) [L. *nux*: kernel or nut] (1) In cells, the centrally located compartment of eukaryotic cells that is bounded by a double membrane and contains the chromosomes. (2) In the brain, an identifiable group of neurons that share common characteristics or functions.

electron A subatomic particle outside the nucleus carrying a negative charge and very little mass.

proton (pro' ton) [Gk. *protos*: first, before] (1) A subatomic particle with a single positive charge. The number of protons in the nucleus of an atom determine its element. (2) A hydrogen ion, H^+ .

neutron (new' tron) One of the three fundamental particles of matter (along with protons and electrons), with mass slightly larger than that of a proton and no electrical charge.

Figure 2.1 The Structure of an Atom An atom has a nucleus composed of neutrons and protons surrounded by a cloud of rapidly moving electrons. Although the nucleus accounts for virtually all of the atomic weight, it occupies only 1/10,000 of the atom's volume. This type of representation, which is called a Bohr model, depicts individual electrons moving in "orbits" at set distances from the nucleus.

The mass of a proton serves as a standard unit of measure called the **dalton** (named after the English chemist John Dalton). A single proton or neutron has a mass of about 1 dalton (Da), which is 1.7×10^{-24} grams (0.0000000000000000000000017 g), but an electron is even tinier at 9×10^{-28} g (0.0005 Da). Because the mass of an electron is negligible compared with the mass of a proton or a neutron, the contribution of electrons to the mass of an atom can usually be ignored when measurements and calculations are made. It is electrons, however, that determine how atoms will combine with other atoms to form stable associations.

dalton (DA) A measure of mass for atoms equal to the atomic mass unit.

Each proton has a positive electric charge, defined as +1 unit of charge. An electron has a negative charge equal and opposite to that of a proton (−1). The neutron, as its name suggests, is electrically neutral, so its charge is 0. Charges that are different (+/−) attract each other, whereas charges that are alike (+/+, −/−) repel each other. Generally, atoms are electrically neutral because the number of electrons in an atom equals the number of protons.

An element consists of only one kind of atom

An **element** is a pure substance that contains only one kind of atom. The element hydrogen consists only of hydrogen atoms; the element iron consists only of iron atoms. The atoms of each element have certain characteristics or properties that distinguish them from the atoms of other elements. These physical and chemical properties (how they interact with other atoms) depend on the numbers of particles the atoms contain.

element A substance that cannot be converted to a simpler substance by ordinary chemical means.

There are 94 elements in nature, and at least another 24 have been made in physics laboratories. About 98 percent of the tissue of every living organism (except in skeletons) is composed of just six elements:

Carbon (symbol C)

Hydrogen (H)

Nitrogen (N)

Oxygen (O)

Phosphorus (P)

Sulfur (S)

The biological roles of these elements will be our major concern in this book, but other elements are found in living organisms as well. Sodium and potassium, for example, are essential for nerve function; calcium can act as a biological signal; iodine is a component of a vital hormone; and magnesium is bound to chlorophyll in plants.

Each element has a unique number of protons

An element differs from other elements by the number of protons in the nucleus of each of its atoms; the number of protons is designated the [atomic number](#). This atomic number is unique to each element and does not change. The atomic number of helium is 2, and an atom of helium always has two protons; the atomic number of oxygen is 8, and an atom of oxygen always has eight protons. Since the number of protons (and electrons) determines how an element behaves in chemical reactions, it is possible to arrange the elements in a table such that those with similar chemical properties are grouped together. This is the familiar [periodic table](#) you see in [Figure 2.2](#).

atomic number The number of protons in the nucleus of an atom; also equals the number of electrons around the neutral atom. Determines the chemical properties of the atom.

periodic table The arrangement of elements in order of increasing atomic number, with vertical groupings of similar valence electrons.

Atomic number (number of protons) 2

Chemical symbol (for helium) He

Atomic weight 4.003

The six elements highlighted in yellow make up 98% of the tissue of most living organisms (except for skeletons).

Elements in the same vertical columns have similar properties in terms of chemical reactions because they have the same number of electrons in their outermost shell.

Elements highlighted in orange are present in small amounts in many organisms.

Masses in parentheses indicate unstable elements that decay rapidly to form other elements.

Figure 2.2 The Periodic Table The periodic table groups all the elements according to their physical and chemical properties. Elements 1–94 occur in nature; elements with atomic numbers greater than 94 were created in the laboratory.

Media Clip 2.1 The Elements Song www.Life11e.com/mc2.1

Along with a definitive number of protons, every element except hydrogen has one or more neutrons in its nucleus. The **mass number** of an atom is the total number of protons and neutrons in its nucleus. The nucleus of a carbon atom contains six protons and six neutrons and has a mass number of 12. Oxygen has eight protons and eight neutrons and has a mass number of 16. Since the mass of an electron is negligible, the mass number is essentially the mass of the atom in daltons.

mass number The sum of the number of protons and neutrons in an atom's nucleus.

By convention, we often print the symbol for an element with the atomic number at the lower left and the mass number at the upper left, both immediately preceding the symbol. Thus hydrogen, carbon, and oxygen can be written as ${}^1_1\text{H}$, ${}^{12}_6\text{C}$, and ${}^{16}_8\text{O}$, respectively.

The number of neutrons differs among isotopes

In some elements, the number of neutrons in the atomic nucleus may vary. Different **isotopes** of the same element have the same number of protons but different numbers of neutrons, as you saw in the story opening this chapter. Many elements have several isotopes. Generally, isotopes are formed when atoms combine and/or release particles (decay). The isotopes of hydrogen shown here have special names, but for most elements their isotopes do not have special names.

isotope (eye' so tope) [Gk. *isos*: equal + *topos*: place] Isotopes of a given chemical element have the same number of protons in their nuclei (and thus are in the same position on the periodic table), but differ in the number of neutrons.

The natural isotopes of carbon, for example, are ${}^{12}\text{C}$ (six neutrons in the nucleus), ${}^{13}\text{C}$ (seven neutrons), and ${}^{14}\text{C}$ (eight neutrons). Note that all three (called carbon-12, carbon-13, and carbon-14) have six protons, so they are all carbon. Most carbon atoms are ${}^{12}\text{C}$, about 1.1 percent are ${}^{13}\text{C}$, and a tiny fraction are ${}^{14}\text{C}$. The carbon atoms that make up complex biological molecules are mostly ${}^{12}\text{C}$, but some are ${}^{13}\text{C}$. The ratio of ${}^{13}\text{C}:$ ${}^{12}\text{C}$ varies with location and can be used to identify biological samples whose origin is not known (**Investigating Life: Determining Beef Source in Big Macs Using Isotope Analysis**). All carbon isotopes have virtually the same chemical reactivity, which is an important property for their use in experimental biology and medicine.

An element's **atomic weight** (or relative atomic mass) is equivalent to the average of the mass numbers of a representative sample of atoms of that element, with all the isotopes in their normally occurring proportions. More precisely, an element's atomic weight is defined as the ratio of the average mass per atom of the element to $1/12$ ^{1/12} of the mass of an atom of ${}^{12}\text{C}$. Because it is a ratio, atomic weight is a dimensionless physical quantity—it is not expressed in units. The atomic weight of hydrogen, taking into account all of its isotopes and their typical abundances, is 1.00794. This number is fractional because it is the average of the contributing masses of all of the isotopes. This definition implies that in any given sample of hydrogen atoms of a particular element found on Earth, the average composition of isotopes will be constant. But as you saw in the opening to this chapter, that is not necessarily so. Some water has more of the heavy O isotopes. So chemists are now listing atomic weights as ranges, for example, H: 1.00784–1.00811.

atomic weight The average of the mass numbers of a representative sample of atoms of an element, with all the isotopes in their normally occurring proportions. Also called atomic mass.

investigatinglife Determining Beef Source in Big Macs Using Isotope Analysis

experiment

Original Paper: Martinelli, L., G. Nardoto, L. Chesson, F. Rinaldi, J. P. H.B. Ometto, T. Cerling and J. Ehleringer, 2011. Worldwide stable carbon and nitrogen isotopes of Big Mac patties: An example of a truly "global" food. *Food Chemistry* 127: 1,712–1,718.

The Big Mac hamburger can be purchased in 35,000 outlets in 120 countries. The recipe for the Big Mac is virtually the same everywhere; it is claimed that the burger has the same quality meat and nutritional quality everywhere it is served. To investigate this claim, Lesley Chesson and

James Ehleringer at the University of Utah compared the ratio of $^{13}\text{C}:^{12}\text{C}$ in Big Mac patties around the world to determine whether the meat had a local or a common source. Beef cattle eat plant food, and carbon atoms from this food end up in meat. In some types of plants, the ratio of $^{13}\text{C}:^{12}\text{C}$ is higher than in others. Depending on which type of plants the cattle consume, the beef will also have a different $^{13}\text{C}:^{12}\text{C}$ ratio.

HYPOTHESIS Beef in Big Macs served in different countries comes from the same source.

METHOD

RESULTS

CONCLUSION The Big Mac burger patties in the two countries have a different isotopic ratio of $^{13}\text{C}:^{12}\text{C}$ atoms, which reflects local sources for the beef. The hypothesis is rejected.

investigatinglife work with the data follows on next page.

work with the data

The experiment compared the meat in Big Macs served in 25 different countries by measuring the ratio of stable carbon isotopes ($^{13}\text{C}:^{12}\text{C}$) in samples of ten beef patties from each country. The hypothesis was based on claims that the beef used in Big Macs comes from a single source, and that the $^{13}\text{C}:^{12}\text{C}$ ratio in patties found everywhere should thus be the same. **Table A** shows the average the $^{13}\text{C}:^{12}\text{C}$ ratio for each of the 25 countries. A higher number means more of the rare, stable isotope ^{13}C than of the much more common ^{12}C .

Table A

Country	$^{13}\text{C}:^{12}\text{C}$ ratio ^a	Country	$^{13}\text{C}:^{12}\text{C}$ ratio	Country	$^{13}\text{C}:^{12}\text{C}$ ratio
All	15.8	Germany	21.7	Portugal	20.7
Argentina	17.2	Hungary	22.0	Scotland	25.2

France	21.8	Paraguay	12.1	Uruguay	16.7

^aMeasured in parts per million atoms ($\times 100$).

QUESTIONS

- Do the average local ratios differ from the 25-country average ratio? What statistical test would you perform to show that the differences between the individual country averages and the all-countries average are significant? (Refer to Appendix B.)
- The countries from which the hamburgers were analyzed are in different locations on Earth. One way to compare locations is by geographic latitude. You may recall that in latitude, 0 degrees defines the equator and 90 degrees defines the poles. **Table B** shows average $^{13}\text{C}:^{12}\text{C}$ ratios of Big Mac beef patties from different latitudes. Plot the data on a graph of ratio versus latitude. What can you conclude from these data?

Table B

Latitude	$^{13}\text{C}:^{12}\text{C}$ ratio ^a
20°S–20°N	11.4
20°–40° ^b	15.3
40°–60° ^b	21.8

^aAverage value measured in parts per million atoms ($\times 100$).

^b20°S–40°S and 20°N–40°N; 40°S–60°S and 40°N–60°N.

A **work with the data** exercise that accompanies this figure may be assigned in **LaunchPad**.

Most isotopes are stable. However, some, called [radioisotopes](#), are unstable and spontaneously give off energy in the form of α (alpha), β (beta), or γ (gamma) radiation from the atomic nucleus. Known as [radioactive decay](#), this release of energy transforms the original atom. The type of transformation varies depending on the radioisotope, but some transformations result in a different number of protons, so that the original atom becomes a different element.

radioisotope A radioactive isotope of an element. Examples are carbon-14 (^{14}C) and hydrogen-3, or tritium (^3H).

radioactive decay Spontaneous disintegration of a substance with the emission of ionizing radiation.

Scientists can detect released radiation from [*radioisotopes](#). For instance, if you feed an earthworm food containing a radioisotope, you can follow the worm's path through the soil by using a detector called a Geiger counter. Most atoms in living organisms are organized into stable associations called [molecules](#). If a radioisotope is incorporated into a molecule, it acts as a tag or label, allowing a researcher or physician to track the molecule in an experiment or in the body ([Figure 2.3](#)).

molecule A chemical substance made up of two or more atoms joined by covalent bonds or ionic attractions.

(A) Depressed

(B) Not depressed

Figure 2.3 Tagging the Brain In these images from live persons, a radioactively labeled sugar is used to detect differences between the brain activity of a depressed

person (A) and that of a person who is not depressed (B). The more active a brain region is, the more sugar it takes up (shown as orange areas). The brain of the depressed person (left) shows less activity than the brain of the person who is not depressed.

Q: How could this technique be used in the clinic?

Although radioisotopes are useful in research and in medicine, even a low dose of the radiation they emit has the potential to damage molecules and cells. However, these damaging effects are sometimes used to our advantage; for example, the radiation from ^{60}Co (cobalt-60) is used in medicine to kill cancer cells.

The behavior of electrons determines chemical bonding and geometry

The number of electrons in an atom determines how it will combine with other atoms. Biologists are interested in how chemical changes take place in living cells. When considering atoms, they are concerned primarily with electrons because the behavior of electrons explains how chemical reactions occur. Chemical reactions alter the atomic compositions of substances and thus alter their properties. Reactions usually involve changes in the distribution of electrons between atoms.

The location of a given electron in an atom at any given time is impossible to determine. We can only describe a volume of space within the atom where the electron is likely to be. The region of space where the electron is found at least 90 percent of the time is the electron's **orbital**. Orbitals have characteristic shapes and orientations, and a given orbital can be occupied by a maximum of two electrons. Thus any atom larger than helium (atomic number 2) must have electrons in two or more orbitals. As we move from lighter to heavier atoms in the periodic table, the orbitals are filled in a specific sequence, in a series of what are known as **electron shells**, or energy levels, around the nucleus.

orbital A region in space surrounding the atomic nucleus in which an electron is most likely to be found.

electron shell The region surrounding the atomic nucleus at a fixed energy level in which electrons orbit.

First shell: The innermost electron shell consists of just one orbital. A hydrogen atom (${}_1\text{H}$) has one electron in its first shell; helium (${}_2\text{He}$) has two. Atoms of all other elements have two or more shells to accommodate orbitals for additional electrons.

Second shell: The second shell contains four orbitals and hence holds up to eight electrons.

Additional shells: Elements with more than ten electrons have three or more electron shells. The farther a shell is from the nucleus, the higher the energy level is for an electron occupying that shell.

Activity 2.1 **Electron Orbitals** www.Life11e.com/ac2.1

The s orbitals fill with electrons first, and their electrons have the lowest energy level. Subsequent shells have different numbers of orbitals, but the outermost shells usually hold only eight electrons. In any atom, the outermost electron shell (the **valence shell**) determines how the atom combines with other atoms—that is, how the atom behaves chemically. When a valence shell with four orbitals contains eight electrons, there are no unpaired electrons and the atom is stable—it is least likely to react with other atoms (**Figure 2.4**). Examples of chemically stable elements are helium, neon, and argon. By contrast, atoms that have one or more

unpaired electrons in their outer shells are capable of reacting with other atoms.

valence shell The outermost energy shell of an atom, containing the valence electrons involved in chemical reactivity.

Figure 2.4 Electron Shells Determine the Reactivity of Atoms Each shell can hold a specific maximum number of electrons. Going out from the nucleus, each shell must be filled before electrons can occupy the next shell. The energy level of an electron is higher in a shell farther from the nucleus. An atom with unpaired electrons in its outermost shell can react (bond) with other atoms. Note that the atoms in this figure are arranged similarly to their arrangement in the periodic table.

Atoms with unpaired electrons (i.e., partially filled orbitals) in their outermost electron shells are unstable and will undergo reactions in order to fill their outermost shells. *Reactive atoms can attain stability either by sharing electrons with other atoms or by losing or gaining one or more electrons.* In either case, the atoms involved are bonded together into stable associations called molecules. The tendency of atoms to form stable molecules so that they have eight electrons in their outermost shells is known as the octet rule. Many atoms in biologically important molecules—for example, carbon (C) and nitrogen (N)—follow this rule. An important exception is hydrogen (H), which attains stability when two electrons occupy its single shell (consisting of just one s orbital).

2.1 recap

Living organisms are composed of the same set of chemical elements as the rest of the universe. An atom consists of a nucleus of protons and neutrons and a characteristic configuration of electrons in orbitals around the nucleus. An atom's chemical properties are determined by its atomic structure.

learning outcomes

You should be able to:

- Compare the elements found in living tissue with elements found in nonliving matter.
- Explain the role that the outermost electron shell plays in determining how an atom may combine with other atoms.
- Explain how elements can be grouped according to their chemical properties in a periodic fashion.

-
1. Describe how the configuration of the valence shell influences the placement of an element in the periodic table.
 2. How does bonding help a reactive atom achieve stability?
 3. Would you expect the elemental composition of Earth's crust to be the same as that of the human body? Explain your answer.

You have been introduced to the individual players on the biochemical stage—the atoms. We have shown how the number of unpaired electrons in an atom's valence shell drives its “quest for stability.” Next we will describe the different types of chemical bonds that can lead to stability—joining atoms together into molecular structures with hosts of different properties.

***connect the concepts** Radioisotopes are also used to analyze biochemical pathways (see [Key Concept 10.3](#)) and to date fossils (see [Key Concept 24.1](#)).

2.2 Atoms Bond to Form Molecules

A **chemical bond** is an attractive force that links two atoms together in a molecule. There are several kinds of chemical bonds (**Table 2.1**). In this section we will begin with covalent bonds, the strong bonds that result from the sharing of electrons. Next we will examine ionic attractions, which form when an atom gains or loses one or more electrons to achieve stability. We will then consider other, weaker kinds of interactions, including hydrogen bonds.

chemical bond An attractive force stably linking two atoms.

table 2.1 Chemical Bonds and Interactions

Name	Basis of interaction	Structure	Bond energy ^a
Covalent bond	Sharing of electron pairs		50–110
Ionic attraction	Attraction of opposite charges		3–7
Hydrogen bond	Electrical attraction between a covalently bonded H atom and an electronegative atom		3–7
Hydrophobic interaction	Interaction of nonpolar substances in the presence of polar substances (especially water)		1–2
van der Waals interaction	Interaction of electrons of nonpolar substances		1

^a Bond energy is the amount of energy in kcal/mol needed to separate two bonded or interacting atoms under physiological conditions.

 Animation 2.1 Chemical Bond Formation www.Life11e.com/a2.1

focus your learning

Covalent bonds are very stable and break only with a large input of energy.

Polar covalent bonds occur when two atoms share bonding electrons in an unequal fashion, whereas nonpolar covalent bonds occur when the bonding electrons are shared equally.

Hydrophilic interactions occur between polar molecules, and hydrophobic interactions occur between nonpolar molecules.

van der Waals forces are weak, noncovalent attractive forces that occur between any two atoms.

Covalent bonds consist of shared pairs of electrons

A **covalent bond** forms when two atoms attain stable electron numbers in their outermost shells by sharing one or more pairs of electrons. Consider two hydrogen atoms coming close to one another, each with an unpaired electron in its single shell (**Figure 2.5**). When the electrons pair up, a stable association is formed, and this links the two hydrogen atoms in a covalent bond, forming the molecule H_2 .

covalent bond Chemical bond based on the sharing of electrons between two atoms.

Figure 2.5 Electrons Are Shared in Covalent Bonds Two hydrogen atoms can combine to form a hydrogen molecule. A covalent bond forms when the electron orbitals of the two atoms overlap in an energetically stable manner.

A **compound** is a pure substance made up of two or more different elements bonded together in a fixed ratio. Chemical symbols identify the different elements in a compound, and subscript numbers indicate how many atoms of each element are present (e.g., H_2O has two atoms of hydrogen bonded to a single oxygen atom). Every compound has a **molecular weight** that is the sum of the atomic weights of all atoms in the molecule. Looking at the periodic table in **Figure 2.2**, you can calculate the molecular weight of water to be 18.01. (But remember that this value comes from the average atomic weights of hydrogen and oxygen; the molecular weight of the heavy water in our opening story is higher because it is formed from heavier isotopes.) Molecules that make up living organisms can have molecular weights of up to half a billion.

compound (1) A substance made up of atoms of more than one element. (2) Made up of many units, as in the **compound eyes** of arthropods.

molecular weight The sum of the atomic weights of the atoms in a molecule.

How are the covalent bonds formed in a molecule of methane gas (CH_4)? The carbon atom has six electrons: two electrons fill its inner shell, and four unpaired electrons travel in its outer shell. Because its outer shell can hold up to eight electrons, carbon can share electrons with up to four other atoms—it can form four covalent bonds (**Focus: Key Figure 2.6A**). When an

atom of carbon reacts with four hydrogen atoms, methane forms. Thanks to electron sharing, the outer shell of methane's carbon atom is now filled with eight electrons, a stable configuration. The outer shell of each of the four hydrogen atoms is also filled. Four covalent bonds—four shared electron pairs—hold methane together. **Focus: Key Figure 2.6B** shows several different ways to represent the molecular structure of methane. **Table 2.2** shows the covalent bonding capacities of some biologically significant elements.

focus: key figure

Ball-and-stick model

The hydrogen atoms form corners of a regular tetrahedron.

Space-filling model

This model shows the shape methane presents to its environment.

(B) Additional ways to show covalent bonding in methane

Figure 2.6 Covalent Bonding Can Form Compounds (A) Bohr models showing the formation of covalent bonds in methane, whose molecular formula is CH_4 . Electrons are shown in shells around the nucleus. (B) Three additional ways of representing the structure of methane. In a structural formula, a covalent bond can be indicated with a single line or a shared pair of electron dots. The ball-and-stick model and the space-filling model show the spatial orientations of the bonds. The space-filling model indicates the overall shape and surface of the molecule. In the chapters that follow, different conventions will be used to depict molecules. Bear in mind that these are models to illustrate certain properties, not accurate portrayals of how atoms would actually appear.

Q: Draw the four representations for carbon dioxide.

table 2.2 Covalent Bonding Capabilities of Some Biologically Important Elements

Element	Usual number of covalent bonds
Hydrogen (H)	1
Oxygen (O)	2
Sulfur (S)	2
Nitrogen (N)	3
Carbon (C)	4

STRENGTH AND STABILITY

Covalent bonds are very strong, meaning that it takes a lot of energy to break them. At temperatures where life exists, the covalent bonds of biological molecules are quite stable, as are their three-dimensional structures. However, this stability does not preclude change, as you will see.

ORIENTATION

For a given pair of elements—for example, carbon bonded to hydrogen—the length of the covalent bond is always the same. And for a given atom within a molecule, the angle of each of its covalent bonds, with respect to the other bonds, is generally the same. This is true regardless of the type of larger molecule that contains the atom. For example, the four filled orbitals around the carbon atom in methane are always distributed in space so that the bonded hydrogen atoms point to the corners of a regular tetrahedron, with carbon in the center (see [Figure 2.6B](#)). Even when carbon is bonded to four atoms other than hydrogen, this three-dimensional orientation is more or less maintained. The orientation of covalent bonds in space gives the molecules their three-dimensional geometry, and the shapes of molecules contribute to their biological functions (see [Key Concept 3.1](#)).

Even though the orientations of bonds around each atom are fairly stable, the shapes of molecules can change. Think of a single covalent bond as an axle around which the two atoms, along with their other bonded atoms, can rotate.

Bond rotation has enormous implications for the large molecules that make up living tissues. Since long chains of atoms (especially carbons) can rotate freely, there are many possibilities for the arrangement of atoms within the chain. This allows molecules to alter their structures, for example, to fit other molecules.

MULTIPLE COVALENT BONDS

Two atoms can share more than one pair of electrons, forming multiple covalent bonds. These can be represented by lines between the chemical symbols for the linked atoms:

A single bond involves the sharing of a single pair of electrons (for example, H—H or C—H).

A double bond involves the sharing of four electrons (two pairs) ($\text{C}=\text{C}$).

Triple bonds—six shared electrons—are rare, but there is one in nitrogen gas ($\text{N}\equiv\text{N}$), which is the major component of the air we breathe.

UNEQUAL SHARING OF ELECTRONS

If two atoms of the same element are covalently bonded, there is an equal sharing of the pair(s) of electrons in their outermost shells. However, when the two atoms are of different elements, the sharing is not necessarily equal. One nucleus may exert a greater attractive force on the electron pair than the other nucleus, so that the pair tends to be closer to that atom.

The attractive force that an atomic nucleus exerts on electrons is called its electronegativity. The **electronegativity** of an atom depends roughly on how many positive charges it has (atoms with more protons are more positive and thus more attractive to electrons) and on the distance between the nucleus and the electrons in the outer (valence) shell (the closer the electrons, the greater the electronegative pull). **Table 2.3** shows the electronegativities (which are calculated to produce dimensionless quantities) of some elements important in biological systems. Note that oxygen (O) is very electronegative; in fact, oxygen is the second most electronegative element (after fluorine). Many organisms exploit the negativity of oxygen; moving electrons between C and O atoms powers living systems, as you will see in many subsequent examples in this text.

electronegativity The tendency of an atom to attract electrons when it occurs as part of a compound.

table 2.3 Some Electronegativities	
Element	Electronegativity
Oxygen (O)	3.5
Chlorine (Cl)	3.1
Nitrogen (N)	3.0
Carbon (C)	2.5
Phosphorus (P)	2.1
Hydrogen (H)	2.1
Sodium (Na)	0.9
Potassium (K)	0.8

If two atoms are close to one another in electronegativity, they will share electrons equally in what is called a **nonpolar covalent bond**. Two oxygen atoms, for example, each with an electronegativity of 3.5, will share electrons equally. So will two hydrogen atoms (each with an electronegativity of 2.1). But when hydrogen bonds with oxygen to form water, the electrons involved are unequally shared; they tend to be nearer to the oxygen nucleus because it is more electronegative than hydrogen. When electrons are drawn to one nucleus more than to the other, the result is a **polar covalent bond** (**Figure 2.7**).

nonpolar covalent bond A covalent bond between atoms that has equal sharing of electrons.

polar covalent bond A covalent bond in which the electrons are drawn to one nucleus more than the other, resulting in an unequal distribution of charge.

Figure 2.7 Water's Covalent Bonds Are Polar These three representations all illustrate polar covalent bonding in water (H_2O). When atoms with different electronegativities, such as oxygen and hydrogen, form a covalent bond, the electrons are drawn to one nucleus more than to the other. A molecule held together by such a polar covalent bond has partial (δ^+ and δ^-) charges at different surfaces. In water, the shared electrons are displaced toward the oxygen atom's nucleus.

Because of this unequal sharing of electrons, the oxygen end of the hydrogen–oxygen bond has a slightly negative charge (symbolized by δ^- and spoken of as “delta negative,” meaning a partial unit of charge), and the hydrogen end has a slightly positive charge (δ^+). The bond is **polar** because these opposite charges are separated at the two ends, or poles, of the bond. The partial charges that result from polar covalent bonds produce polar molecules or polar regions of large molecules. Polar bonds within molecules greatly influence the interactions they have with other polar molecules. Water (H_2O) is a polar compound, and this polarity has significant effects on its physical properties and chemical reactivity, as you will see in later chapters.

polar A molecule with separate and opposite electric charges at two ends, or poles; the water molecule (H_2O) is the most prevalent example. (Contrast with nonpolar.)

Ionic attractions form by electrical attraction

When one interacting atom is much more electronegative than the other, a complete transfer of one or more electrons may take place. Consider sodium (electronegativity 0.9) and chlorine (electronegativity 3.1). A sodium atom has only one electron in its outermost shell; this condition is unstable. A chlorine atom has seven electrons in its outermost shell—another unstable condition. Since the electronegativity of chlorine is so much greater than that of sodium, any electrons involved in bonding will tend to transfer completely from sodium's outermost shell to that of chlorine (**Figure 2.8**). This reaction between sodium and chlorine makes the resulting atoms more stable because they both have eight fully paired electrons in their outer shells. The result is two ions.

Figure 2.8 Formation of Sodium and Chloride Ions When a sodium atom reacts with a chlorine atom, the more electronegative chlorine fills its outermost shell by “stealing” an electron from the sodium. In so doing, the chlorine atom becomes a negatively charged chloride ion (Cl⁻). With one less electron, the sodium atom becomes a positively charged sodium ion (Na⁺).

Q: What ions are formed when calcium ion reacts with chlorine? See the periodic table in [Figure 2.2](#).

Ions are electrically charged particles that form when atoms gain or lose one or more electrons:

ion (eye’ on) [Gk. *ion*: wanderer] An electrically charged particle that forms when an atom gains or loses one or more electrons.

The sodium ion (Na⁺) in our example has a +1 unit of charge because it has one less electron than it has protons. The outermost electron shell of the sodium ion is full, with eight electrons, so the ion is stable. Positively charged ions are called **cations**. Other biologically important cations include Ca²⁺, H⁺, Mg²⁺, and K⁺.

The chloride ion (Cl⁻) has a –1 unit of charge because it has one more electron than it has protons. This additional electron gives Cl⁻ a stable outermost shell with eight electrons.

Negatively charged ions are called [anions](#).

cation (cat' eye on) An ion with one or more positive charges. (Contrast with anion.)

anion (an' eye on) [Gk. *ana*: upward] A negatively charged ion. (Contrast with cation.)

Some elements can form ions with multiple charges by losing or gaining more than one electron. Examples are Ca^{2+} (the calcium ion, a calcium atom that has lost two electrons) and Mg^{2+} (the magnesium ion). Two biologically important elements can each yield more than one stable ion. Iron yields Fe^{2+} (the ferrous ion) and Fe^{3+} (the ferric ion), and copper yields Cu^+ (the cuprous ion) and Cu^{2+} (the cupric ion). Groups of covalently bonded atoms that carry an electric charge are called [complex ions](#); examples include NH_4^+ (the ammonium ion), SO_4^{2-} (the sulfate ion), and PO_4^{3-} (the phosphate ion). Once formed, ions are usually stable and no more electrons are lost or gained.

complex ions Groups of covalently bonded atoms that carry an electric charge (e.g., NH_4^+ , the ammonium ion).

[Ionic attractions](#) are bonds formed as a result of the electrical attraction between ions bearing opposite charges. Ions can form bonds that result in stable solid compounds, which we call salts. You're familiar with sodium chloride (NaCl)—table salt; its cations (Na^+) and anions (Cl^-) are held together by ionic attractions. In solids, the attractions are strong because the ions are close together. However, when ions are dispersed in water, the distances between them can be large, greatly reducing the strength of the attraction. Under the conditions in living cells, an ionic attraction is less strong than a covalent bond (see [Table 2.1](#)).

ionic attraction An electrostatic attraction between positively and negatively charged ions.

Not surprisingly, ions can interact with polar molecules, since both are charged. This interaction results when a solid salt such as NaCl dissolves in water. Water molecules surround the individual ions, separating them ([Figure 2.9](#)). The negatively charged chloride ions attract the positive poles of the water molecules, while the positively charged sodium ions attract the negative poles of the water molecules. This special property of water (its polarity) is one reason it is such a good biological solvent (see [Key Concept 2.4](#)).

Figure 2.9 Water Molecules Surround Ions When an ionic solid dissolves in water, polar water molecules cluster around the cations and anions, preventing them from reassociating.

Q: What happens at the chemical and physical levels when a salt solution evaporates?

Hydrogen bonds may form within or between molecules with polar covalent bonds

In liquid water, the negatively charged oxygen (δ^-) atom of one water molecule is attracted to the positively charged hydrogen (δ^+) atoms of another water molecule (**Figure 2.10A**). The bond resulting from this attraction is called a **hydrogen bond**. Later in this chapter you'll see how hydrogen bonding between water molecules contributes to many of the properties that make water so important for living systems. Hydrogen bonds are not restricted to water molecules. Such a bond can also form between a strongly electronegative atom in one molecule and a hydrogen atom that is involved in a polar covalent bond in another molecule, or another part of the same molecule (**Figure 2.10B**).

Figure 2.10 Hydrogen Bonds Can Form between or within Molecules (A) A hydrogen bond between two molecules is an attraction between a negative charge on one molecule and the positive charge on a hydrogen atom of the second molecule. (B) Hydrogen bonds can form between different parts of the same large molecule.

Q: What happens to a large molecule if increasing heat is applied? Which bonds or interactions are affected?

hydrogen bond A weak electrostatic bond which arises from the attraction between the slight positive charge on a hydrogen atom and a slight negative charge on a nearby oxygen or nitrogen atom.

A hydrogen bond is weaker than most ionic attractions because its formation is due to partial charges (δ^+ and δ^-). It is much weaker than a covalent bond between a hydrogen atom and an oxygen atom (see [Table 2.1](#)). Although individual hydrogen bonds are weak, there can be many of them within a single molecule or between two molecules. In these cases, the hydrogen bonds together have considerable strength and can greatly influence the structure and properties of substances. For example, hydrogen bonds play important roles in determining and maintaining the three-dimensional shapes of giant molecules such as DNA and proteins (see [Key Concept 3.2](#)).

Hydrophobic interactions bring together nonpolar molecules

Just as water molecules can interact with one another through hydrogen bonds, any molecule that is polar can interact with other polar molecules through the weak (δ^+ to δ^-) attractions of hydrogen bonds. If a polar molecule interacts with water in this way, it is called **hydrophilic** ("water-loving") ([Figure 2.11A](#)).

hydrophilic (high dro fill' ik) [Gk. *hydro*: water + *philia*: love] Having an affinity for water. (Contrast with hydrophobic.)

Nonpolar molecules, in contrast, tend to interact with other non-polar molecules. For example, carbon (electronegativity 2.5) forms nonpolar bonds with hydrogen (electronegativity 2.1), and molecules containing only hydrogen and carbon atoms—called **hydrocarbon molecules**—are

nonpolar. In water these molecules tend to aggregate with one another rather than with the polar water molecules. Therefore nonpolar molecules are known as **hydrophobic** (“water-hating”), and the interactions between them are called **hydrophobic interactions** (**Figure 2.11B**). Of course, hydrophobic substances do not really “hate” water; they can form weak interactions with it, since the electronegativities of carbon and hydrogen are not exactly the same. But these interactions are far weaker than the hydrogen bonds between the water molecules (see **Table 2.1**), so the nonpolar substances tend to aggregate.

hydrocarbon A compound containing only carbon and hydrogen atoms.

hydrophobic (high dro foe' bik) [Gk. *hydro*: water + *phobia*: fear] Having no affinity for water. Uncharged and nonpolar groups of atoms are hydrophobic. (Contrast with hydrophilic.)

hydrophobic interaction A weak chemical interaction caused when molecules that are not attracted to water interact to exclude water.

(A) Hydrophilic

(B) Hydrophobic

Figure 2.11 Hydrophilic and Hydrophobic (A) Molecules with polar covalent bonds are attracted to polar water (they are hydrophilic). (B) Molecules with nonpolar covalent bonds show greater attraction to one another than to water (they are hydrophobic).

van der Waals forces involve contacts between atoms

The interactions between nonpolar substances are enhanced by [van der Waals forces](#), which occur when the atoms of two molecules are in close proximity. These brief interactions result from random variations in the electron distribution in one molecule, which can create opposite charge distributions in the adjacent molecule. So there will be a weak, temporary δ^+ to δ^- attraction. van der Waals forces occur in polar and nonpolar molecules. In the latter case, they can induce cohesion between molecules that do not form ionic attractions or hydrogen bonds. Although a single van der Waals interaction is brief and weak, the sum of many such interactions over the entire span of a large nonpolar molecule can result in substantial attraction. This is important when hydrophobic regions of different molecules such as an enzyme and a substrate come together (see [Chapter 8](#)).

van der Waals forces Weak attractions between atoms resulting from the interaction of the electrons of one atom with the nucleus of another. This type of attraction is about one-fourth as strong as a hydrogen bond.

2.2 recap

Some atoms form strong covalent bonds with other atoms by sharing one or more pairs of electrons. Unequal sharing of electrons produces polarity. Other atoms become ions by losing or gaining electrons, and they interact with other ions or polar molecules. Weak forces such as hydrogen bonds also act to attract atoms to one another.

learning outcomes

You should be able to:

- Explain why covalent bonds are so strong.
- Identify examples of polar covalent and nonpolar covalent bonds.
- Distinguish between hydrophilic and hydrophobic interactions using examples.
- Identify instances in which van der Waals forces are important.

1. Why is a covalent bond stronger than an ionic attraction when a molecule is in water?
2. Consider the following pairs of bonded atoms:

For each pair, use [Tables 2.2](#) and [2.3](#) to determine:

- a. whether the bond is polar or nonpolar
- b. if the bond is polar, which end is δ^-
- c. whether the atom pair contributes hydrophilic or hydrophobic properties to a molecule

3. Geckos are lizards that are amazing climbers. A gecko can climb up a glass surface and stick to it with a single toe. Professor Kellar Autumn at Lewis and Clark College and his students and collaborators have shown that each toe of a gecko has millions of micrometer-sized hairs, and that each hair splits into hundreds of 200-nano-meter tips that provide intimate contact with a surface. Careful measurements show that a million of these tips could easily support the animal, but it has far more. The toes stick well on hydrophilic and hydrophobic surfaces. Bending the hairs allows the gecko to detach. What kind of noncovalent force is involved in gecko sticking?

The bonding of atoms into molecules is not necessarily a permanent affair. The dynamic aspect of life involves constant change, even at the molecular level. In the next section we will examine how molecules interact with one another—how they break up, how they find new partners, and what the consequences of those changes can be.

2.3 Atoms Change Partners in Chemical Reactions

A hallmark of life is that it is dynamic. Things don't sit still, especially at the chemical level. Atoms bonded to other atoms can leave a binding relationship and find a new partner. Bear in mind that this does not happen all the time: your skin is a biological tissue, and its atoms form a stable structure. But change is common, especially among the atoms and molecules dissolved in water. A [chemical reaction](#) occurs when moving atoms collide with sufficient energy to combine or to change their bonding partners.

chemical reaction The change in the composition or distribution of atoms of a substance with consequent alterations in properties.

focus your learning

Chemical reactions obey the laws of conservation of energy and conservation of matter.
Chemical reactions are accompanied by changes in energy.

Consider the combustion reaction that takes place in the flame of a propane stove. When propane (C_3H_8) reacts with oxygen gas (O_2), the carbon atoms become bonded to oxygen atoms instead of hydrogen atoms, and the hydrogen atoms become bonded to oxygen instead of carbon ([Figure 2.12](#)). As the covalently bonded atoms change partners, the composition of the matter changes; propane and oxygen gas become carbon dioxide and water. This chemical reaction can be represented by the equation

Reactants $\rightarrow$ Products

Figure 2.12 Bonding Partners and Energy May Change in a Chemical Reaction

One molecule of propane (a gas used for cooking) from this burner reacts with five molecules of oxygen gas to give three molecules of carbon dioxide and four molecules of water. This reaction releases energy in the form of heat and light.

In this equation, propane and oxygen are the [reactants](#), and carbon dioxide and water are the [products](#). This example is an [oxidation-reduction \(redox\) reaction](#)—a special type of chemical reaction that involves a transfer of electrons between two species:

The electron acceptor, or oxidizing agent, gains electrons and is said to be *reduced* in a chemical reaction.

The electron donor, or reducing agent, loses electrons and is said to be *oxidized* in a chemical reaction.

reactant A chemical substance that enters into a chemical reaction with another substance.

products The molecules that result from the completion of a chemical reaction.

oxidation–reduction (redox) reaction A reaction in which one substance transfers one or more electrons to another substance. (See oxidation, reduction.)

Can you identify the oxidizing and reducing agents in our example? Because electrons and protons (i.e., hydrogen atoms) are transferred *from* propane, propane is the reducing agent and oxygen is the oxidizing agent, which in this example forms water upon accepting the hydrogens. You will see many examples of redox reactions involving electron/proton transfer in later chapters.

The products of a chemical reaction can have very different properties from the reactants. The reaction shown in [Figure 2.12](#) is said to be *complete*: all the propane and oxygen are used up in forming the two products. The arrow symbolizes the direction of the chemical reaction. The numbers preceding the molecular formulas indicate how many molecules are used or produced.

Note that in this and all other chemical reactions, *matter is neither created nor destroyed*. The total number of carbon atoms on the left side of the equation (3) equals the total number of carbon atoms on the right (3). In other words, the equation is *balanced*. However, there is

another aspect of this reaction: the heat and light of the stove's flame reveal that the reaction between propane and oxygen releases a great deal of energy.

Energy is defined as the capacity to do work, but in the context of chemical reactions, it can be thought of as the capacity for change. Chemical reactions do not create or destroy energy, but *changes in the form of energy* usually accompany chemical reactions.

energy The capacity to do work or move matter against an opposing force. The capacity to accomplish change in physical and chemical systems.

In the reaction between propane and oxygen, a large amount of heat energy is released. This energy was present in another form, called potential chemical energy, in the covalent bonds within the propane and oxygen gas molecules. Not all reactions release energy; indeed, many chemical reactions require that energy be supplied from the environment. Some of this energy is then stored as potential chemical energy in the bonds formed in the products. We will see in future chapters how reactions that release energy and reactions that require energy are often coupled.

Many chemical reactions take place in living cells, and some of these have a lot in common with the oxidation-reduction reaction we saw in the combustion of propane. In cells, the reactants are different (they may be sugars or fats), and the reactions proceed by many intermediate steps that permit the released energy to be harvested and put to use by the cells. But the products are the same: carbon dioxide and water.

2.3 recap

In a chemical reaction, a set of reactants is converted to a set of products with different chemical compositions. A chemical reaction involves breaking old bonds and making new ones. A reaction may release energy or require its input.

learning outcomes

You should be able to:

- Demonstrate an example to show that chemical reactions obey the law of conservation of matter.
- Explain how energy is involved in a chemical reaction.

1. Using the example of the chemical equation $\text{C}_6\text{H}_{12}\text{O}_6 + \text{O}_2 \rightarrow \text{CO}_2 + \text{H}_2\text{O}$, insert numbers so that the numbers of atoms on both sides of the equation are balanced.

2. Use an example to explain how the form of energy can change during a chemical reaction.

We will return to chemical reactions and how they occur in living systems in [Chapter 8](#), [9](#), and [10](#), focusing particularly on energy transformations that fuel biological processes. First, however, we will examine the unique properties of the substance in which most biochemical reactions take place: water.

2.4 Water Is Critical for Life

Your body is more than 70 percent water by weight, excluding the minerals contained in bones. Water is the dominant component of virtually all living organisms, and most biochemical reactions take place in this watery, or aqueous, environment. Water is an unusual substance with unusual properties. Under conditions on Earth, water exists in solid, liquid, and gas forms, all of which have relevance to living systems. Water allows chemical reactions to occur inside living organisms, and it is necessary for the formation of certain biological structures. In this section we will explore how the structure and interactions of water molecules make water essential to life.

focus your learning

Biochemical reactions within cells occur in an aqueous environment.

Moles are used to quantify substances in biological fluids.

The acid-base properties of water and other compounds in cells allow reversible changes that affect biological functions.

Water has a unique structure and special properties

The molecule H_2O has unique chemical features. As you have already learned, water is a polar molecule that can form hydrogen bonds. The four pairs of electrons in the outer shell of the oxygen atom repel one another, giving the water molecule a tetrahedral shape:

The chemical features of water explain some of its interesting properties, such as the ability of ice to float, the melting and freezing temperatures of water, the ability of water to store heat, the formation of water droplets, water's ability to dissolve many substances, and its inability to dissolve many others.

ICE FLOATS

In water's solid state (ice), individual water molecules are held in place by hydrogen bonds. Each molecule is bonded to four other molecules in a rigid, crystalline structure ([Figure 2.13](#)). Although the molecules are held firmly in place, they are farther apart from one another than they are in liquid water, where the molecules are moving about. In ice, there are cavities between individual water molecules. In other words, solid water is less dense than liquid water, which is why ice floats.

Figure 2.13 Hydrogen Bonding and the Properties of Water Hydrogen bonding occurs between the molecules of water in both its liquid and solid states. Ice is more structured but less dense than liquid water, which is why ice floats. Water forms a gas when its hydrogen bonds are broken and the molecules move farther apart.

Think of the biological consequences if ice were to sink in water. A pond would freeze from the bottom up, becoming a solid block of ice in winter and killing most of the organisms living there. Once the whole pond was frozen, its temperature could drop well below the freezing point of water. But because ice floats, it forms an insulating layer on the top of the pond, and reduces heat flow to the cold air above. Thus fish, plants, and other organisms in the pond are not subjected to temperatures lower than 0°C , which is the freezing point of pure water.

MELTING, FREEZING, AND HEAT CAPACITY

Compared with many other substances that have molecules of similar size, ice requires a great deal of heat energy to melt. The amount of heat energy required to raise the temperature of 1 gram of a substance by 1°C is called its **specific heat**. Water has a relatively high specific heat because so many hydrogen bonds connecting the water molecules in ice must be broken to change water from solid to liquid. In the opposite process—freezing—a great deal of energy is released to the environment. We say water has a high heat capacity. For example, water has twice the specific heat of ethyl alcohol and five times that of sand. This is why when you are on the beach as the sun sets, the sand cools much more quickly than the water.

specific heat The amount of energy that must be absorbed by a gram of a substance to raise its temperature by one degree centigrade. By convention, water is assigned a specific heat of one.

Because it takes a lot of energy to change the physical state of water, water temperatures in oceans and other large bodies of water are remarkably constant throughout the year. The temperature changes of coastal land masses are in turn moderated by large bodies of water. Indeed, water helps minimize variations in atmospheric temperature across the planet. Water's ability to moderate heat helps it function as an insulator, helping prevent an organism's body temperature from rising during a sunny day.

Water also has a high **heat of vaporization**, which means that a lot of heat is required to change water from its liquid to its gaseous state (the process of evaporation). Once again, much of the heat energy is used to break the many hydrogen bonds between the water molecules. This heat must be absorbed from the environment in contact with the water. ***Evaporation** thus has a cooling effect on the environment—whether a leaf, a forest, or an entire land mass. This effect explains why sweating cools the human body: as sweat evaporates from the skin, it uses up some of the adjacent body heat (**Figure 2.14A**).

heat of vaporization The energy that must be supplied to convert a molecule from a liquid to a gas at its boiling point.

(A)

High heat of vaporization:

Sweating uses evaporation of water to cool the body.

(B)

Cohesion: Water's

cohesive strength helps it to flow from the roots to the leaves in a tree.

(C)

Surface tension: Water molecules stick to one another and help prevent this wolf spider from sinking.

Figure 2.14 Water in Biology These three properties of water make it beneficial to organisms.

COHESION AND SURFACE TENSION

In liquid water, individual molecules are able to move about. The hydrogen bonds between the molecules continually form and break (see [Figure 2.14](#)). Chemists estimate that this occurs about a trillion times a minute for a single water molecule!

At any given time, a water molecule forms on average 3.4 hydrogen bonds with other water molecules. These hydrogen bonds explain the cohesive strength of liquid water. This cohesive strength, or [cohesion](#), is defined as the capacity of water molecules to resist coming apart from one another when placed under tension. Water's [*cohesive strength](#) permits narrow columns of liquid water to move from the roots to the leaves of tall trees. When water evaporates from the leaves, the entire column moves upward in response to the pull of the molecules at the top ([Figure 2.14B](#)). A related property is [adhesion](#), the attraction of water molecules to other molecules of a different type. For example, when you put a straw into a cup with water, it “climbs” up the straw so the column is higher than the level in the cup. This adhesive behavior of water—sticking to the sides of the straw—reflects the adhesion of water forming the column.

cohesion The tendency of molecules (or any substances) to stick together.

adhesion Binding of one cell or substance to another.

The surface of liquid water exposed to the air is difficult to puncture because the water molecules at the surface are hydrogen-bonded to other water molecules below them. This surface tension of water permits a container to be filled slightly above its rim without overflowing, and it permits spiders to walk on the surface of a pond ([Figure 2.14C](#)).

The reactions of life take place in aqueous solutions

A [solution](#) is produced when a substance (the [solute](#)) is dissolved in a liquid (the [solvent](#)). If the solvent is water, then the solution is called an aqueous solution. As you know by now, water is polar. Because many important molecules in biological systems are polar, they readily dissolve in water. Being soluble doesn't mean that the molecules lose their identity and properties. They can still react, and indeed many important biochemical reactions occur in aqueous solutions.

solution A liquid (the solvent) and its dissolved solutes.

solute A substance that is dissolved in a liquid (solvent) to form a solution.

solvent Liquid in which a substance (solute) is dissolved to form a solution.

Biologists who are interested in the biochemical reactions within cells identify the reactants and products and determine their amounts using two different types of analyses:

- *Qualitative analyses* focus on identifying the substances involved in chemical reactions. For example, a qualitative analysis would be used to investigate the steps involved and the products formed during respiration, when carbon-containing compounds are broken down to release energy in living tissues.
- *Quantitative analyses* measure concentrations or amounts of substances. For example, a biochemist would use a quantitative analysis to measure how much of a certain product is formed in a chemical reaction. What follows is a brief introduction to some of the quantitative chemical terms you will see in this book.

Fundamental to quantitative thinking in chemistry and biology is the concept of the mole. A **mole** is the amount of a substance (in grams) that is numerically equal to its molecular weight. So a mole of hydrogen gas (H_2) weighs 2 g, a mole of sodium ion (Na^+) weighs 23 g, and a mole of table sugar ($\text{C}_{12}\text{H}_{22}\text{O}_{11}$) weighs about 342 g.

mole A quantity of a compound whose weight in grams is numerically equal to its molecular weight expressed in atomic mass units. Avogadro's number of molecules: 6.023×10^{23} molecules.

Quantitative analyses do not yield counts of molecules. Because the amount of a substance in 1 mole is directly related to its molecular weight, it follows that the number of molecules in 1 mole is constant for all substances. So 1 mole of salt contains the same number of molecules as 1 mole of table sugar. This constant number of molecules in a mole is called **Avogadro's number**, and it is 6.02×10^{23} molecules per mole. Chemists work with moles of substances (which can be weighed in the laboratory) instead of actual molecules, which are too numerous to be counted. Consider 34.2 g (just over 1 ounce) of table sugar, $\text{C}_{12}\text{H}_{22}\text{O}_{11}$. This is one-tenth of a mole, or one-tenth of Avogadro's number: 6.02×10^{22} molecules.

Avogadro's number The number of atoms or molecules in a mole (weighed out in grams) of a substance, calculated to be 6.023×10^{23} .

A chemist can dissolve 1 mole of table sugar (342 g) in water to make 1 liter of solution, knowing that the mole contains 6.02×10^{23} individual sugar molecules. This solution—1 mole of a substance dissolved in water to make 1 liter—is called a 1 molar (1 M) solution. When a physician injects a certain volume and molar concentration of a drug into the bloodstream of a patient, a rough calculation can be made of the actual number of drug molecules that will interact with the patient's cells. As you know, the dose is important.

The many molecules dissolved in the water of living tissues are not present at concentrations anywhere near 1 molar. Most are in the micromolar (millionths of a mole per liter of solution; μM) to millimolar (thousandths of a mole per liter; mM) range. Some, such as hormone molecules, are even less concentrated than that. While these molarities seem to indicate very low concentrations, remember that even a 1 μM solution has 6.02×10^{17} molecules of the solute per

liter.

Aqueous solutions may be acidic or basic

When some substances dissolve in water, they release hydrogen ions (H^+), which are actually single, positively charged protons. Hydrogen ions can interact with other molecules and change their properties. For example, the protons in “acid rain” can damage plants, and you probably have experienced the excess of hydrogen ions that we call “acid indigestion.”

Here we will examine the properties of **acids** (defined as substances that release H^+) and **bases** (defined as substances that accept H^+). We will distinguish between strong and weak acids and bases, and provide a quantitative means for stating the concentration of H^+ in solutions: the pH scale.

acid [L. *acidus*: sharp, sour] A substance that can release a proton in solution. (Contrast with base.)

base (1) A substance that can accept a hydrogen ion in solution. (Contrast with acid.) (2) In nucleic acids, the purine or pyrimidine that is attached to each sugar in the sugar–phosphate backbone.

ACIDS RELEASE H^+

When hydrochloric acid (HCl) is added to water, it dissolves, releasing the ions H^+ and Cl^- :

Because its H^+ concentration has increased, the solution is acidic.

Acids are substances that *release* H^+ ions in solution. HCl is an acid, as is H_2SO_4 (sulfuric acid). One molecule of sulfuric acid will ionize to yield two H^+ and one SO_4^{2-} . Biological compounds that contain —COOH (called a carboxyl group) are acids because the carboxyl group can ionize to —COO^- , releasing H^+ :

Acids that fully ionize in solution, such as HCl and H_2SO_4 , are called strong acids. However, not all acids ionize fully in water. For example, if acetic acid (CH_3COOH) is added to water, some of it will dissociate into two ions (CH_3COO^- and H^+), but some of the original acetic acid will remain as well. Because the reaction is not complete, acetic acid is a weak acid.

BASES ACCEPT H^+

Bases are substances that *accept* H^+ in solution. As with acids, there are strong and weak bases. If NaOH (sodium hydroxide) is added to water, it dissolves and ionizes, releasing OH^- and Na^+ ions:

Because OH^- absorbs H^+ to form water, such a solution is basic. This reaction is complete, and so NaOH is a strong base.

Weak bases include the bicarbonate ion (HCO_3^-), which can accept an H^+ ion and become

carbonic acid (H_2CO_3), and ammonia (NH_3), which can accept H^+ and become an ammonium ion (NH_4^+). Biological compounds that contain —NH_2 (the amino group) are also bases because —NH_2 accepts H^+ :

ACID–BASE REACTIONS MAY BE REVERSIBLE

When acetic acid is dissolved in water, two reactions happen. First, the acetic acid forms its ions:

Then, once the ions are formed, some of them re-form acetic acid:

This pair of reactions is reversible. A **reversible reaction** can proceed in either direction—left to right or right to left—depending on the relative starting concentrations of the reactants and products. The formula for a reversible reaction can be written using a double arrow:

reversible reaction A chemical transformation that can occur in either direction, so that reactants become products and vice versa.

In terms of acids and bases, there are two types of reactions, depending on the extent of the reversibility:

- . The ionization of strong acids and bases in water is virtually irreversible.
- . The ionization of weak acids and bases in water is somewhat reversible.

WATER IS A WEAK ACID AND A WEAK BASE

The water molecule has a slight but significant tendency to ionize into a hydroxide ion (OH^-) and a hydrogen ion (H^+). Actually, two water molecules participate in this reaction. One of the two molecules “captures” a hydrogen ion from the other molecule, forming a hydroxide ion and a hydronium ion:

The hydronium ion is, in effect, a hydrogen ion bound to a water molecule. For simplicity, biochemists tend to use a modified representation of the ionization of water:

The ionization of water is important to all living creatures. This fact may seem surprising, since only about 1 water molecule in 500 million is ionized at any given time. But this is less surprising if we focus on the abundance of water in living systems, and the reactive nature of the H^+ ions produced by ionization.

pH: HYDROGEN ION CONCENTRATION

As we have seen, compounds can be either acids or bases, and thus solutions can be either acidic or basic. We can measure how acidic or basic a solution is by measuring its concentration of H^+ in moles per liter (its molarity; see [p. 36](#)). Here are some examples:

Pure water has a H^+ concentration of 10^{-7} M.

A 1 M HCl solution has a H^+ concentration of 1 M (recall that all the HCl dissociates into its ions).

A 1 M NaOH solution has a H^+ concentration of 10^{-14} M.

This is a very wide range of numbers to work with—think about the decimals! It is easier to work with the logarithm of the H^+ concentration, because logarithms compress this range: the $\log_{10}$ of 100, for example, is 2; and the $\log_{10}$ of 0.01 is -2. Because most H^+ concentrations in living systems are less than 1 M, their $\log_{10}$ values are negative. For convenience, we convert these negative numbers into positive ones by using the *negative* of the logarithm of the H^+ molar concentration. This number is called the [pH](#) of the solution:

$$\text{pH} = -\log(\text{H}^+) \text{ where } (\text{H}^+) \text{ is the concentration of free } \text{H}^+ \text{ in solution}$$

pH The negative logarithm of the hydrogen ion concentration; a measure of the acidity of a solution. A solution with $\text{pH} = 7$ is said to be neutral; pH values higher than 7 characterize basic solutions, while acidic solutions have pH values less than 7.

Since the H^+ concentration of pure water is 10^{-7} M, its pH is $-\log(10^{-7}) = -(-7)$, or 7. A smaller negative logarithm means a larger number. In practical terms, a lower pH means a higher H^+ concentration, or greater acidity. In 1 M HCl, the H^+ concentration is 1 M, so the pH is the negative logarithm of 1 ($-\log 1$), or 0. The pH of 1 M NaOH is the negative logarithm of 10^{-14} , or 14.

A solution with a pH of less than 7 is acidic—it contains more H^+ ions than OH^- ions. A solution with a pH of 7 is referred to as neutral, and a solution with a pH value greater than 7 is basic. [Figure 2.15](#) shows the pH values of some common substances.

Figure 2.15 pH Values of Some Familiar Substances

Why is this discussion of pH so relevant to biology? Many reactions involve the transfer of an ion or charged group from one molecule to another, and the presence of positive or negative ions in the environment can greatly influence the rates of such reactions. Furthermore, pH can influence the shapes of molecules. Many biologically important molecules contain charged groups (e.g., —COO^-) that can interact with the polar regions of water, and these interactions influence the way such molecules fold up into three-dimensional shapes. If these charged groups combine with H^+ or other ions in their environment to form uncharged groups (e.g., —COOH ; see above), they will have a reduced tendency to interact with water. These uncharged

(hydrophobic) groups might induce the molecule to fold up differently so that they are no longer in contact with the watery environment. Since the three-dimensional structures of biological molecules greatly affect the way they function, organisms do all they can to minimize changes in the pH of their cells and tissues. An important way to do this is with buffers.

BUFFERS

The maintenance of internal constancy—homeostasis—is a hallmark of all living things and extends to pH. If biological molecules lose or gain H^+ ions, their properties can change, thus upsetting homeostasis. For example, people who exercise strenuously produce lactic acid, which ionizes to produce H^+ . Internal constancy within tissues can be achieved with buffers: solutions that maintain a relatively constant pH even when substantial amounts of acid or base are added. How does this work?

A **buffer** is a mixture of a weak acid and its corresponding base, or a weak base and its corresponding acid. For example, a weak acid is carbonic acid (H_2CO_3), and its corresponding base is the bicarbonate ion (HCO_3^-). If another acid is added to a solution containing this mixture (a buffered solution), not all the H^+ ions from the acid remain in solution. Instead, many of them combine with the bicarbonate ions to produce more carbonic acid:

buffer A substance that can transiently accept or release hydrogen ions and thereby resist changes in pH.

This reaction uses up some of the H^+ ions in the solution and decreases the acidifying effect of the added acid. If a base is added, the reaction essentially reverses. Some of the carbonic acid ionizes to produce bicarbonate ions and more H^+ , which counteracts some of the added base. The buffer minimizes the effect that an added acid or base has on pH. The carbonic acid/bicarbonate buffering system is present in the blood, where it is important for preventing significant changes in pH that could disrupt the ability of the blood to carry vital oxygen to tissues. A given amount of acid or base causes a smaller pH change in a buffered solution than in a non-buffered one (**Figure 2.16**).

Figure 2.16 Buffers Minimize Changes in pH When base is added to a solution, the pH of the solution increases. Without a buffer, the change is large and the slope of the pH graph is steep. In the presence of a buffer, however, the slope within the buffering range is shallow.

Buffers illustrate an important chemical principle of reversible reactions, called the [law of mass action](#). Addition of a reactant on one side of a reversible system drives the reaction in the direction that uses up that compound. In the case of buffers, addition of an acid drives the reaction in one direction; addition of a base drives the reaction in the other direction.

law of mass action The rate of a chemical reaction is directly proportional to the concentrations of the reacting substances.

You may occasionally use a buffer to relieve indigestion. The lining of the stomach constantly secretes hydrochloric acid, making the stomach contents acidic. But excessive stomach acid can cause discomfort. We can relieve this discomfort by ingesting a salt such as $NaHCO_3$ (sodium bicarbonate), which acts as a buffer.

2.4 recap

Most of the chemistry of life occurs in water, which has unique properties that make it an ideal medium for supporting life. These properties include hydrogen bonding between molecules, high specific heat, and cohesion between molecules. Aqueous solutions can be acidic or basic, depending on the concentration of hydrogen ions. The cells and tissues of organisms are buffered, however, because changes in pH can change the properties of

biological molecules.

learning outcomes

You should be able to:

- Explain why water's solvent properties are important in understanding events taking place inside cells.
- Perform quantitative analyses of biochemical compounds using the mole concept.
- Predict and explain changes in pH caused by changes in concentration of weak acids or bases in living tissue.

1. What is a solution, and why do we call water "the medium of life"?
2. A substance in a cell has a concentration of 0.00000001 molar. What does this mean in terms of the number of molecules in a cell that has a volume of 0.000001 liters?
3. In human tissues, CO_2 is formed as a by-product of oxidation of more complex molecules. CO_2 enters the blood-stream and in red blood cells is removed from the blood by the reaction $\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{HCO}_3^- + \text{H}^+$. What is the consequence of this reaction on the pH of the blood? What chemical reaction would restore the pH of the blood?

investigatinglife

What insights into biological systems have been discovered through isotope analysis?

The opening investigation of dinosaurs (oxygen atoms) and the investigating life experiment of hamburgers (carbon atoms) are examples of identifying the life history of organisms through isotopic analysis. Recently, this has been applied to humans as well. Hair is a living tissue, with a lot of O and H atoms derived from water in the diet. Ecologist Jim Ehleringer and chemist Thure Cerling have shown that like the dinosaurs, the isotopic ratios of O and H in hair reflect the geographical region where a person drank the water. This can be useful evidence in a forensic investigation, placing a person at a location. Isotopic ratios are also used to identify where plants are grown, because their tissues also have unique ratios. For example, ratios have revealed the geographical origin of poppies used to make heroin. The mass spectrometer, a chemical analysis instrument that detects isotopes, is fast becoming an important tool for biologists.

Future directions

Tracking the isotopes of oxygen and hydrogen in precipitation is useful in understanding patterns of climate change. Water evaporates in warmer regions at the tropical latitudes on Earth and moves toward the cooler poles. As an air mass moves from a warmer to a cooler region, water vapor condenses and is removed as precipitation. The heavy isotopes of H and O tend to fall as precipitation more readily than the lighter isotopes, so as the water vapor moves toward the poles, it becomes enriched in the lighter isotopes. The ratio of heavy to light isotopes that reach the poles depends on the climate—the cooler the climate, the lower the ratio, because more water precipitates as it moves toward the poles, depleting more of the heavier isotopes. Analyses of polar ice cores show that heavy-to-light isotope ratios vary over geological time scales. This has allowed scientists to reconstruct climate change in the past, and to relate it to fossil organisms that lived at those times. Isotope ratios may be useful in monitoring climate change that is happening today.

► 2.1 Atomic Structure Explains the Properties of Matter

- Matter is composed of atoms. Each **atom** consists of a positively charged nucleus made up of **protons** and **neutrons**, surrounded by **electrons** bearing negative charges.

Review Figure 2.1

atom [Gk. *atomos*: indivisible] The smallest unit of a chemical element. Consists of a nucleus and one or more electrons.

proton (pro' ton) [Gk. *protos*: first, before] (1) A subatomic particle with a single positive charge. The number of protons in the nucleus of an atom determine its element. (2) A hydrogen ion, H^+ .

neutron (new' tron) One of the three fundamental particles of matter (along with protons and electrons), with mass slightly larger than that of a proton and no electrical charge.

electron A subatomic particle outside the nucleus carrying a negative charge and very little mass.

- The number of protons in the nucleus defines an **element**. There are many elements in the universe, but only a few of them make up the bulk of living organisms: C, H, O, P, N, and S. **Review Figure 2.2**

element A substance that cannot be converted to a simpler substance by ordinary chemical means.

- Isotopes** of an element differ in their numbers of neutrons. **Radioisotopes** are radioactive, emitting radiation as they break down.

isotope (eye' so tope) [Gk. *isos*: equal + *topos*: place] Isotopes of a given chemical element have the same number of protons in their nuclei (and thus are in the same position on the periodic table), but differ in the number of neutrons.

radioisotope A radioactive isotope of an element. Examples are carbon-14 (^{14}C) and hydrogen-3, or tritium (^3H).

- Electrons are distributed in **electron shells**, which are volumes of space defined by specific numbers of orbitals. Each **orbital** contains a maximum of two electrons. **!!Review Figure 2.4, Activity 2.1**

electron shell The region surrounding the atomic nucleus at a fixed energy level in which electrons orbit.

orbital A region in space surrounding the atomic nucleus in which an electron is most likely to be found.

- In losing, gaining, or sharing electrons to become more stable, an atom can combine with

other atoms to form a [molecule](#).

molecule A chemical substance made up of two or more atoms joined by covalent bonds or ionic attractions.

▶ 2.2 Atoms Bond to Form Molecules

- A [chemical bond](#) is an attractive force that links two atoms together in a molecule. !![Review Table 2.1](#), [Animation 2.1](#)

chemical bond An attractive force stably linking two atoms.

- A [compound](#) is a substance made up of molecules with two or more different atoms bonded together in a fixed ratio, such as water (H₂O).

compound (1) A substance made up of atoms of more than one element. (2) Made up of many units, as in the **compound eyes** of arthropods.

- [Covalent bonds](#) are strong bonds formed when two atoms share one or more pairs of electrons. !![Review Figure 2.5](#), [Focus: Key Figure 2.6](#)

covalent bond Chemical bond based on the sharing of electrons between two atoms.

- When two atoms of unequal electronegativity bond with each other, a [polar covalent bond](#) is formed. The two ends, or poles, of the bond have partial charges (δ^+ or δ^-). [Review Figure 2.7](#)

polar covalent bond A covalent bond in which the electrons are drawn to one nucleus more than the other, resulting in an unequal distribution of charge.

- An [ion](#) is an electrically charged particle that forms when an atom gains or loses one or more electrons in order to form a more stable electron configuration. [Anions](#) and [cations](#) are negatively and positively charged ions, respectively. Different charges attract each other, and like charges repel each other.

ion (eye' on) [Gk. *ion*: wanderer] An electrically charged particle that forms when an atom gains or loses one or more electrons.

anion (an' eye on) [Gk. *ana*: upward] A negatively charged ion. (Contrast with cation.)

cation (cat' eye on) An ion with one or more positive charges. (Contrast with anion.)

- [Ionic attractions](#) occur between oppositely charged ions. Ionic attractions are strong in solids (salts) but weaken when the ions are separated from one another in solution. [Review Figure 2.9](#)

ionic attraction An electrostatic attraction between positively and negatively charged ions.

- A **hydrogen bond** is a weak electrical attraction that forms between a δ^+ hydrogen atom in one molecule and a δ^- atom in another molecule (or in another part of the same, large molecule). Hydrogen bonds are abundant in water. **Review Figure 2.10**

hydrogen bond A weak electrostatic bond which arises from the attraction between the slight positive charge on a hydrogen atom and a slight negative charge on a nearby oxygen or nitrogen atom.

- Nonpolar molecules interact very little with polar molecules, including water. Nonpolar molecules are attracted to one another by very weak bonds called **van der Waals forces**.

van der Waals forces Weak attractions between atoms resulting from the interaction of the electrons of one atom with the nucleus of another. This type of attraction is about one-fourth as strong as a hydrogen bond.

▶ 2.3 Atoms Change Partners in Chemical Reactions

- In **chemical reactions**, atoms combine or change their bonding partners. **Reactants** are converted into **products**.

chemical reaction The change in the composition or distribution of atoms of a substance with consequent alterations in properties.

reactant A chemical substance that enters into a chemical reaction with another substance.

products The molecules that result from the completion of a chemical reaction.

- Some chemical reactions release **energy** as one of their products; other reactions can occur only if energy is provided to the reactants.

energy The capacity to do work or move matter against an opposing force. The capacity to accomplish change in physical and chemical systems.

- Neither matter nor energy is created or destroyed in a chemical reaction, but both change form. **Review Figure 2.12**
- In organisms, chemical reactions take place in multiple steps so that released energy can be harvested for cellular activities.

▶ 2.4 Water Is Critical for Life

- Water's molecular structure and its capacity to form hydrogen bonds give it unique properties that are significant for life. **Review Figure 2.13**
- The high **specific heat** of water means that water gains or loses a great deal of heat when it changes state. Water's high **heat of vaporization** ensures effective cooling when water evaporates.

specific heat The amount of energy that must be absorbed by a gram of a substance to raise its temperature by one degree centigrade. By convention, water is assigned a specific heat of one.

heat of vaporization The energy that must be supplied to convert a molecule from a liquid to a

gas at its boiling point.

- The **cohesion** of water molecules refers to their capacity to resist coming apart from one another. Hydrogen bonding between the water molecules plays an essential role in this property.

cohesion The tendency of molecules (or any substances) to stick together.

- A **solution** is produced when a solid substance (the solute) dissolves in a liquid (the **solvent**). Water is the critically important solvent for life. The ability of molecules to lose or accept protons (H^+) is important in biological structure and function.

solution A liquid (the solvent) and its dissolved solutes.

solvent Liquid in which a substance (solute) is dissolved to form a solution.

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify your understanding of this chapter. **LearningCurve** adapts to your responses, giving you the practice you need to master each key concept.

Review

- 4 The acid-base properties of water and other compounds in cells allow reversible changes that affect biological functions

Scientists are developing methods to sample a person's breath and test it for higher-than-normal levels of compounds that contain ketones. The buildup of these compounds in the body can indicate type I diabetes. This work could lead to development of a portable device that will allow earlier diagnosis of diabetes, especially in children.

Insulin is a hormone that stimulates cells in the body to take up glucose from the blood. Cells use glucose as a source of energy for normal cell function. In type I diabetes, insulin is not produced, and glucose does not enter cells from the blood. Lacking an incoming supply of glucose, cells begin breaking down fats as a source of energy. When fats break down, several ketone-containing compounds are produced and they can be detected by a breath analysis device. A ketone has the general structure RCOR' , where R and R' are the same or different groups of atoms.

One of the ketone-containing products of fat breakdown is aceto-acetic acid, which has the structure below. Acetoacetic acid is very harmful when it builds up in high concentration in the body.

Questions

1. In water, acetoacetic acid can ionize to form protons and aceto-acetate ions. Write the chemical structures for this reaction.
2. Now write out the reversible chemical reaction for the ionization of carbonic acid in blood, which can act as a buffer. Would the pH of blood change if a small amount of acetoacetic acid produced normally in tissues were added to the blood? Explain.
3. What would happen to the pH of the blood if more and more acetoacetic acid built up, as in a case of untreated diabetes? Explain, using what you found in Question 2 above. What would happen to the body's ability to maintain a constant blood pH? How does this explain why people with this condition become severely ill?
4. Acetone is one of the compounds produced from fat breakdown and expelled in the breath. It is targeted for detection by a breath-analysis device. Its chemical structure is shown below. Analyze the structure to determine whether it would be expected to affect the carbonic acid or bicarbonate buffer system in the blood.

5. Suppose scientists succeed in developing a device that detects ketone buildup in the breath. If a person tested positive for higher-than-normal ketones with the breath test, what are some blood tests that could be done to follow up? Suggest three or four different blood tests, other than acetoacetic acid or ketone levels, that could be used to detect the existence of insulin insufficiency. Describe the outcome of each test in the case of a positive result.

***connect the concepts** Living systems use the evaporation of water, which disrupts hydrogen bonds, to dissipate excess heat that would otherwise cause problems. See [Key Concept 38.3](#) for examples in plants, and [Key Concepts 39.3–39.5](#) for examples in animals.

***connect the concepts** As described in [Key Concept 34.2](#), the transpiration–cohesion–tension mechanism accounts for the movement of water from roots to leaves. Because of the cohesion between water molecules, water is pulled upward in continuous columns.

Weaving a Web

A spider web is an amazing structure. It is not only beautiful to look at, but an architectural wonder serving as the spider's home, its mating place, and its way to capture food.

Consider a fly that chances to interact with a spider web. The fibers of the web must slow down the fly, but they cannot break, so they need to stretch to dissipate the energy of the fly's movement. The fibers holding the fly cannot stretch too much; they must be strong enough to hold the web in place. Web fibers are far thinner than a human hair, yet they are very strong. The fibers can also be long; for example, the Darwin's bark spider makes strands up to 25 meters long.

Chemical investigations reveal that spider silk is made of variations on a single type of large molecule called a protein. Proteins are polymers: long chains of individual smaller units called amino acids. The proteins in spider silks have characteristic structures and amino acid compositions that determine particular functions. Proteins in the stretchy web fibers have amino acids that allow them to curl into spirals, and these spirals can slip along one another to change the fiber's length. Another kind of spider silk is the dragline silk, which is less stretchy and used to construct the outline of the web, its spokes, and the lifeline of the spider. The proteins in these strong fibers are made up of amino acids that cause the proteins to fold into flat sheets with ratchets, so that parallel sheets can fit together like Lego blocks. This arrangement makes these fibers hard to pull apart.

Just how strong is spider silk? A popular series of films features the fictional character Spider-Man. He often uses his web to ensnare evildoers and protect the innocent. In one scene, he stops a train by using ten ropes made of spider silk, each about 1 centimeter thick. Scientists who study spider silk have estimated the number of silk fibers in each rope and calculated that this scene would indeed be possible. All of this from covalent bonds holding long chains of amino acids together and weaker forces between the chains! Given the amazing strength shown by these proteins, it is not surprising that there is a lot of interest in using spider silk for human activities.

What are practical uses for spider silk?

3.1 Macromolecules Characterize Living Things

Four kinds of molecules are characteristic of living things: proteins, carbohydrates, lipids, and nucleic acids. With the exception of the lipids, these biological molecules are **polymers** (*poly*, “many,” + *mer*, “unit”) constructed by the covalent bonding of smaller molecules called **monomers**. Each kind of biological molecule is made up of monomers with similar chemical structures:

polymer [Gk. *poly*: many + *meros*: unit] A large molecule made up of similar or identical subunits called monomers. (Contrast with monomer.)

monomer [Gk. *mono*: one + *meros*: unit] A small molecule, two or more of which can be combined to form oligomers (consisting of a few monomers) or polymers (consisting of many monomers).

Proteins are formed from different combinations of 20 amino acids, all of which share chemical similarities.

Carbohydrates can form giant molecules by linking together chemically similar sugar monomers (monosaccharides) to form polysaccharides.

Nucleic acids are formed from four kinds of nucleotide monomers linked together in long chains.

Lipids also form large structures from a limited set of smaller molecules, but in this case noncovalent forces maintain the interactions between the lipid monomers that are held together by covalent bonds.

Polymers containing thousands or more atoms are called **macromolecules**. The proteins, carbohydrates, and nucleic acids of living systems certainly fall into this category. Although large lipid structures are not polymers in the strictest sense, it is convenient to treat them as macromolecules (see [Key Concept 3.4](#)). Green plants have the living world's most abundant protein (rubisco; see [Chapter 10](#)), most abundant carbohydrate (cellulose in plant cell walls), and most abundant lipid (monogalactosyl diglyceride in leaves).

macromolecule A giant (molecular weight > 1,000) polymeric molecule. The macromolecules are the proteins, polysaccharides, and nucleic acids.

focus your learning

Isomers are molecules having the same composition but different structures.

Monomers are chemically linked via condensation reactions to form polymers.

Chemical groupings determine the structures of macromolecules

Certain small groups of atoms, called **functional groups**, occur frequently in biological molecules ([Figure 3.1](#)). Each functional group has specific chemical properties, and when it is attached to a larger molecule, it confers those properties on the larger molecule. One of these

properties is polarity. Looking at the structures in [Figure 3.1](#), can you determine which functional groups are the most polar? (Hint: look for C—O, N—H, and P—O bonds.) The consistent chemical behavior of functional groups helps us understand the properties of the molecules that contain them.

functional group (1) A characteristic combination of atoms that contributes specific properties (such as charge or polarity) when attached to larger molecules (e.g., carboxyl group, amino group). (2) A group of species that function in similar ways, whether or not they use the same resources. (Compare with guild.)

Functional group	Class of compounds and an example	Properties
Hydroxyl $\text{R}-\text{OH}$	Alcohols $\begin{array}{c} \text{H} \quad \text{H} \\ \quad \\ \text{H}-\text{C}-\text{C}-\text{OH} \\ \quad \\ \text{H} \quad \text{H} \end{array}$ Ethanol	Polar. Forms hydrogen bonds with water to help dissolve molecules. Enables linkage to other molecules by condensation.
Aldehyde $\text{R}-\text{C}(=\text{O})\text{H}$	Aldehydes $\begin{array}{c} \text{H} \quad \text{O} \\ \quad \\ \text{H}-\text{C}-\text{C}-\text{H} \\ \quad \\ \text{H} \quad \text{H} \end{array}$ Acetaldehyde	Polar. C=O group is very reactive. Important in building molecules and in energy-releasing reactions.
Keto $\text{R}-\text{C}(=\text{O})-\text{R}$	Ketones $\begin{array}{c} \text{H} \quad \text{O} \quad \text{H} \\ \quad \quad \\ \text{H}-\text{C}-\text{C}-\text{C}-\text{H} \\ \quad \quad \\ \text{H} \quad \text{H} \quad \text{H} \end{array}$ Acetone	Polar. C=O group is important in carbohydrates and in energy reactions.
Carboxyl $\text{R}-\text{C}(=\text{O})\text{OH}$	Carboxylic acids $\begin{array}{c} \text{H} \quad \text{O} \\ \quad \\ \text{H}-\text{C}-\text{C}-\text{OH} \\ \quad \\ \text{H} \quad \text{H} \end{array}$ Acetic acid	Charged; acidic. Ionizes in living tissues to form $-\text{COO}^-$ and H^+ . Enters into condensation reactions by giving up $-\text{OH}$. Some carboxylic acids important in energy-releasing reactions.
Amino $\text{R}-\text{N}(\text{H})_2$	Amines $\begin{array}{c} \text{H} \quad \text{H} \\ \quad \\ \text{H}-\text{C}-\text{N}-\text{H} \\ \quad \\ \text{H} \quad \text{H} \end{array}$ Methylamine	Charged; basic. Accepts H^+ in living tissues to form $-\text{NH}_3^+$. Enters into condensation reactions by giving up H^+ .
Phosphate $\text{R}-\text{O}-\text{P}(=\text{O})(\text{O}^-)_2$	Organic phosphates $\begin{array}{c} \text{O}^- \quad \text{O} \\ \diagdown \quad // \\ \text{C} \\ \\ \text{H}-\text{C}-\text{OH} \\ \\ \text{H}-\text{C}-\text{O}-\text{P}(=\text{O})(\text{O}^-)_2 \\ \\ \text{H} \end{array}$ 3-Phosphoglycerate	Charged; acidic. Enters into condensation reactions by giving up $-\text{OH}$. When bonded to another phosphate, hydrolysis releases much energy.
Sulfhydryl $\text{R}-\text{SH}$	Thiols $\begin{array}{c} \text{H} \quad \text{H} \\ \quad \\ \text{HO}-\text{C}-\text{C}-\text{SH} \\ \quad \\ \text{H} \quad \text{H} \end{array}$ Mercaptoethanol	By giving up H, two $-\text{SH}$ groups can react to form a disulfide bridge, thus stabilizing protein structure.
Methyl $\text{R}-\text{CH}_3$	Alkyl $\begin{array}{c} \text{H} \\ \\ \text{H}_3\text{N}^+-\text{C}-\text{COO}^- \\ \\ \text{CH}_3 \end{array}$ Alanine	Nonpolar. Important in interacting with other nonpolar molecules and in energy transfer.

Figure 3.1 Some Functional Groups Important to Living Systems Highlighted here are the eight functional groups most commonly found in biologically important molecules. “R” is a variable chemical grouping.

 Activity 3.1 **Functional Groups** www.Life11e.com/ac3.1

 Animation 3.1 **Proteins, Carbohydrates, and Lipids** www.Life11e.com/a3.1

Macromolecules have many different functional groups. A single large protein may contain nonpolar, polar, and charged functional groups, each of which gives different specific properties to local sites on the macromolecule. As we will see, sometimes these different groups interact within the same macromolecule. They help determine the shape of the macromolecule as well as how it interacts with other macromolecules and with smaller molecules.

Using the same atoms, molecules can differ from one another because their functional groups can be arranged differently. **Isomers** are molecules that have the same (“iso”) chemical formula — the same kinds and numbers of atoms—but with the atoms arranged differently. Of the different kinds of isomers, we will consider three: structural isomers, *cis-trans* isomers, and optical isomers.

isomers Molecules consisting of the same numbers and kinds of atoms, but differing in the bonding patterns by which the atoms are held together.

Structural isomers differ in how their atoms are joined together. Consider two simple molecules, each composed of four carbon and ten hydrogen atoms bonded covalently, both with the formula C_4H_{10} . These atoms can be linked in two different ways, resulting in different molecules (**Figure 3.2A**).

structural isomers Molecules made up of the same kinds and numbers of atoms, in which the atoms are bonded differently.

(A) Structural isomers

(B) *cis-trans* isomers

(C) Optical isomers

Figure 3.2 Isomers Isomers have the same chemical formula, but the atoms are arranged differently. Pairs of isomers often have different chemical properties and functions.

- ***cis-trans* isomers** typically involve a double bond between two carbon atoms, where the carbons share two pairs of electrons. When the remaining two bonds of each of these carbons are to two different atoms or groups of atoms (e.g., a hydrogen and a methyl group; [Figure 3.2B](#)), these can be oriented on the same side or different sides of the double-bonded molecule. If the different atoms or groups of atoms are on the same side, the double bond is called *cis*; if they are on opposite sides, the bond is *trans*. These molecules can have very different properties.

***cis-trans* isomers** In molecules with a double bond (typically between two carbon items), identifies on which side of the double bond similar atoms or functional groups are found. If they are on the same side, the molecule is a *cis* isomer; in a *trans* isomer, similar atoms are on opposite sides of the double bond. (See isomers.)

- **Optical isomers** occur when a carbon atom has four different atoms or groups of atoms attached to it. This pattern allows for two different ways of making the attachments, each the mirror image of the other ([Figure 3.2C](#)). Such a carbon atom is called an asymmetric carbon, and the two resulting molecules are optical isomers of one another. You can envision your right and left hands as optical isomers. Just as a glove is specific for a particular hand, some biochemical molecules that can interact with one optical isomer of a carbon compound are unable to “fit” the other.

optical isomers Two molecular isomers that are mirror images of each other.

The structures of macromolecules reflect their functions

The four kinds of biological macromolecules are present in roughly the same proportions in all living organisms ([Figure 3.3](#)). Also, a protein that has a certain structure, and therefore function, in an apple tree probably has a similar structure and function in a human being, because the protein’s chemistry is the same wherever it is found. This impressive biochemical unity reflects the evolution of all life from a common ancestor, by descent with modification. An important advantage of biochemical unity is that some organisms can acquire needed raw materials by eating other organisms. When you eat an apple, the molecules you take in include carbohydrates, lipids, and proteins that can be broken down and rebuilt into the varieties of those molecules needed by humans.

Figure 3.3 Substances Found in Living Tissues The substances shown here make up the nonmineral components of living tissues (bone would be an example of a mineral component).

Each kind of macromolecule performs one or more functions such as energy storage, structural support, catalysis (speeding up of chemical reactions), transport of other molecules, regulation of other molecules, defense, movement, or information storage. These roles are not necessarily exclusive; for example, both carbohydrates and proteins can play structural roles, supporting and protecting tissues and organs. However, only the nucleic acids specialize in information storage and transmission. These macromolecules function as hereditary material, carrying the traits of both species and individuals from generation to generation.

experiment

Original Paper: Teule, F., Y.-G. Miao, B.-H. Sohn, Y.-S. Kim, J. Hull, M. J. Fraser, R. V. Lewis and D. L. Jarvis, 2012. Silkworms transformed with chimeric silkworm/spider silk genes spin composite silk fibers with improved mechanical properties. *Proceedings of the National Academy of Sciences USA*. 109: 923–928.

Spider silk is one of the strongest materials known, but it is very hard to harvest in quantity. Industrial biologists are therefore using genetic engineering to produce the protein fibers. The scientists have coaxed silkworms, insect larvae that make silk fibers used in clothing, to make a much stronger composite of silkworm and spider silk.

HYPOTHESIS▶ Genetically engineered silkworms can produce silk with physical properties like those of silk made by spiders.

METHOD

RESULTS Both silks had identical physical properties of stress (force needed to break) and strain (stretching).

CONCLUSION▶ Silkworms can make composite silk fiber with the same properties as those of the native spider silk protein.

work with the data

Spider silk is a protein-based material that is very strong because of its secondary structure. Because of its potential uses by humans, it is desirable to obtain large amounts of these fibers. Spiders spin out the silk fibers for their web, but the amounts are insufficient for human use. Silkworms make abundant silk fibers that are used in textiles but are much weaker than spider silk. An international team of scientists led by Randy Lewis at the University of Wyoming genetically engineered silkworms to make composite silkworm–spider silk fibers in large quantities. They then tested the properties of these fibers and compared them with those of native spider silk.

QUESTIONS

1. To evaluate the properties of the protein fibers, researchers stretched them and measured the forces involved as well as the resulting lengthening of the fibers. You can liken this to stretching a rubber band until it breaks. Stress is the force required to break the fiber; it is measured in millipascals (mPa; 1 Pa is the force in newtons per unit area in m^2). Strain is a measure of how much the fiber lengthens (as a percentage of its original length). **Table A** compares the results from silk from spiders and from genetically engineered silkworms. Did the genetically engineered silkworms make fibers that were similar to native spider silk?
2. Why was thickness (diameter) reported in the data?
3. What statistical test would you perform to determine if the measured properties were significantly different (see Appendix B)?
4. The scientists measured the properties composite of spider silk compared with those of Kevlar (a synthetic fiber with many uses, including in bicycle tires, racing sails, and body armor) and steel. The results are shown in **Table B**. What can you conclude about the spider silk?

Table A

Silk	Diameter (μm)	Max. strain (%)
Silkworms	21.8 ± 1.6	22.0 ± 5.8
Silkworms, gen. engineer.	21.1 ± 1.4	31.8 ± 5.2
Spiders	8.1 ± 0.4	19.7 ± 4.8

Table B

Material	Energy required to break filament (joules/kg)	Weight (g/mm^3)
Spider silk	120,000	1.3
Kevlar	40,000	1.4
Steel	3,500	7.84

A similar **work with the data** exercise may be assigned in **LaunchPad**.

The sequence and chemical properties of the chain of monomers in a macromolecule determine its three-dimensional shape and function. Some macromolecules fold into compact forms with surface features that make them water-soluble and capable of intimate interactions with other molecules. Some proteins and carbohydrates form long, fibrous structures (such as those found in spider silk or hair) that provide strength and rigidity. The specific structure of a macromolecule determines its function in a given environment, regardless of its origin. For example, composite spider silk fiber made by another organism (e.g., the silkworm, a moth larva) has the same properties as spider silk made by a spider (**Investigating Life: Making Spider Silk**).

Most macromolecules are formed by condensation and broken down by

hydrolysis

Polymers are formed from monomers by a series of [condensation reactions](#) (in this case called dehydration reactions; both terms refer to the loss of water). Condensation reactions result in the formation of covalent bonds between monomers. A molecule of water is released with each covalent bond formed ([Figure 3.4A](#)). The condensation reactions that produce the different kinds of polymers differ in detail, but in all cases polymers form only if water molecules are removed and energy is added to the system. In living systems, specific energy-rich molecules supply the necessary energy.

condensation reaction A chemical reaction in which two molecules become connected by a covalent bond and a molecule of water is released ($AH + BOH \rightarrow AB + H_2O$.) (Contrast with hydrolysis reaction.)

(A) Condensation reactions produce water.

(B) Hydrolysis reactions consume water.

Figure 3.4 Condensation and Hydrolysis of Polymers (A) Condensation reactions link monomers into polymers and produce water. (B) Hydrolysis reactions break polymers into individual monomers and consume water.

The reverse of a condensation reaction is a [hydrolysis reaction](#) (*hydro*, “water,” + *lysis*, “break”). Hydrolysis reactions result in the breakdown of polymers into their component

monomers. Water reacts with the covalent bonds that link the polymer together. For each covalent bond that is broken, a water molecule splits into two ions (H^+ and OH^-), each of which becomes part of one of the products ([Figure 3.4B](#)).

hydrolysis reaction (high drol' uh sis) [Gk. *hydro*: water + *lysis*: break apart] A chemical reaction that breaks a bond by inserting the components of water ($\text{AB} + \text{H}_2\text{O} \rightarrow \text{AH} + \text{BOH}$). (Contrast with condensation reaction.)

3.1 recap

The four kinds of large molecules that distinguish living tissues are proteins, lipids, carbohydrates, and nucleic acids. Most are polymers: chains of linked monomers. Very large polymers are called macromolecules. Biological molecules carry out a variety of life-sustaining functions.

learning outcomes

You should be able to:

- Distinguish between structural, *cis-trans*, and optical isomers.
- Give an example of two molecules that have the same functional groups but different properties, and explain the reason for the differences.
- Sketch the chemical structures of two biological monomers, and show how a condensation reaction produces a covalent bond between the two.

4. What are the differences between structural, *cis-trans*, and optical isomers?
5. Examine the isomers mannose and galactose below. What makes them isomers of each other? Which functional groups do these carbohydrates contain, and what properties do these functional groups give to the molecules?

6. Below are the general structures of three monomers in a biological polymer where A, B, and C are numerous atoms. Draw the reaction that links them together to form a polymer ABC.

The four types of macromolecules can be seen as the building blocks of life. We will cover the unique properties of the nucleic acids in [Chapter 4](#). The remainder of this chapter will describe

the structures and functions of the proteins, carbohydrates, and lipids.

3.2 The Function of a Protein Depends on Its Three-Dimensional Structure

Proteins have very diverse roles. You'll learn about the many functions of proteins ([Table 3.1](#)) in virtually every chapter of this book. [Proteins](#) are polymers made up of 20 amino acids in different proportions and sequences. Proteins range in size, from small ones such as the human hormone insulin, which has 51 amino acids and a molecular weight of 5,733, to huge molecules such as the muscle protein titin, with 26,926 amino acids and a molecular weight of 2,993,451. Proteins consist of one or more **polypeptide chains**—unbranched (linear) polymers of covalently linked amino acids. Variation in the sequences of amino acids in the polypeptide chains allows for the vast diversity in protein structure and function. Each chain folds into a particular three-dimensional shape that is specified by the sequence of amino acids present in the chain.

table 3.1 Proteins and Their Functions	
Category	Function
Enzymes	Catalyze (speed up) biochemical reactions
Structural proteins	Provide physical stability and movement
Defensive proteins	Recognize and respond to nonself substances (e.g., antibodies)
Signaling proteins	Control physiological processes (e.g., hormones)
Receptor proteins	Receive and respond to chemical signals
Membrane transporters	Regulate passage of substances across cellular membranes
Storage proteins	Store amino acids for later use
Transport proteins	Bind and carry substances within the organism
Gene regulatory proteins	Determine the rate of expression of a gene
Motor proteins	Cause movement of structures in the cell

protein (pro' teen) [Gk. *protos*: first] Long-chain polymer of amino acids with twenty different common side chains. Occurs with its polymer chain extended in fibrous proteins, or coiled into a compact macromolecule in enzymes and other globular proteins. The component amino acids are encoded in the triplets of messenger RNA, and proteins are the products of genes.

focus your learning

A protein's tertiary structure describes its three-dimensional shape and is stabilized by hydrogen bonds, hydrophobic interactions, ionic attractions, and in some proteins, disulfide bonds.

Exposed surface groups on a protein provide both shapes and chemical groups that can interact specifically with other molecules or ions.

The forces that stabilize a protein's secondary, tertiary, and quaternary structures make the

protein vulnerable to disruption by environmental factors.

Monomers of proteins link together to make the macromolecule

Each **amino acid** has both a carboxyl functional group and an amino functional group (see [Figure 3.1](#)) attached to the same carbon atom, called the α (alpha) carbon. Also attached to the α carbon atom are a hydrogen atom and a **side chain**, or **R group**, designated by the letter R.

amino acid An organic compound containing both NH_2 and COOH groups. Proteins are polymers of amino acids.

side chain See R group.

R group The distinguishing group of atoms of a particular amino acid; also known as a side chain.

The α carbon in this example is asymmetrical because it is bonded to four different atoms or groups of atoms. Therefore amino acids can exist as optical isomers called D-amino acids and L-amino acids. D and L are abbreviations of the Latin terms for right (*dextro*) and left (*levo*). Only L-amino acids (with the configuration shown above) are commonly found in the proteins of most organisms, and their presence is an important chemical “signature” of life.

At the pH levels typically found in cells (usually about pH 7), both the carboxyl and amino groups of amino acids are ionized: the carboxyl group has lost a hydrogen ion:

and the amino group has gained a hydrogen ion:

Thus amino acids are simultaneously acids and bases.

Activity 3.2 Features of Amino Acids www.Life11e.com/ac3.2

The side chains (or R groups) of amino acids contain functional groups that are important in determining the three-dimensional structure and thus the function of the protein. As [Table 3.2](#) shows, the 20 amino acids found in living organisms are grouped and distinguished by their side chains:

table 3.2 The Twenty Amino Acids

(A) Amino acids with electrically charged hydrophilic side chains

(B) Amino acids with polar but uncharged side chains (hydrophilic)

(C) Special cases

(D) Amino acids with nonpolar hydrophobic side chains

Five amino acids have electrically charged (ionized) side chains at pH levels typical of living cells. These side chains attract water (are hydrophilic) and attract oppositely charged ions of all

sorts.

Five amino acids have polar side chains. They are also hydrophilic and attract other polar or charged molecules.

Seven amino acids have side chains that are nonpolar and thus hydrophobic. In the watery environment of the cell, these hydrophobic groups may cluster together in the interior of the protein.

Three amino acids—cysteine, glycine, and proline—are special cases, although the side chains of the latter two are generally hydrophobic.

The cysteine side chain, which has a terminal —SH group, can react with another cysteine side chain in an oxidation reaction to form a covalent bond ([Figure 3.5](#)). Such a bond, called a **disulfide bridge** or disulfide bond (—S—S—), helps determine how a polypeptide chain folds.

Figure 3.5 A Disulfide Bridge Two cysteine molecules in a polypeptide chain can form a disulfide bridge (—S—S—) by oxidation (removal of H atoms).

disulfide bridge The covalent bond between two sulfur atoms (—S—S—) linking two molecules or remote parts of the same molecule.

The glycine side chain consists of a single hydrogen atom. It is small enough to fit into tight corners in the interiors of protein molecules where larger side chains could not fit.

Proline possesses a modified amino group that lacks a hydrogen atom and instead forms a covalent bond with the hydrocarbon side chain, resulting in a ring structure. This limits both its hydrogen-bonding ability and its ability to rotate around the α carbon. So proline is often found where a protein bends or loops.

Peptide linkages form the backbone of a protein

Linking amino acids involves a reaction between carboxyl and amino groups attached to the α carbon. The carboxyl group of one amino acid reacts with the amino group of another, undergoing a condensation reaction that forms a **peptide linkage** (also called a peptide bond). **Figure 3.6** depicts this reaction.

peptide linkage The bond between amino acids in a protein; formed between a carboxyl group and amino group (—CO—NH—) with the loss of water molecules.

Figure 3.6 Formation of Peptide Linkages In living things, the dehydration reaction leading to a peptide linkage (also called a peptide bond) has many intermediate steps, but the reactants and products are the same as those shown in this simplified diagram.

Just as a sentence begins with a capital letter and ends with a period, polypeptide chains have a beginning and an end. The “capital letter” marking the beginning of a polypeptide is the amino group of the first amino acid added to the chain and is known as the N terminus. The “period” is the carboxyl group of the last amino acid added; this is the C terminus.

Two characteristics of the peptide bond are especially important in the three-dimensional structures of proteins:

- In the C—N linkage, the adjacent α carbons ($\alpha \text{ C—C—N—}\alpha \text{ C}$) are not free to rotate fully, which limits the folding of the polypeptide chain.
- The oxygen bound to the carbon (C=O) in the carboxyl group carries a slight negative charge (δ^-), whereas the hydrogen bound to the nitrogen (N—H) in the amino group is slightly positive (δ^+). This asymmetry of charge favors hydrogen bonding within the protein molecule itself and between molecules. These bonds contribute to the structures and functions of many proteins.

In addition to these characteristics of the peptide linkage, the particular sequence of amino acids—with their various R groups—in the polypeptide chain also plays a vital role in determining a protein’s structure (**Focus Key Figure 3.7A**) and function.

Level	Description	Stabilized by	Example
(A) Primary	Amino acid monomers are joined, forming polypeptide chains.	Peptide bonds	
(B) Secondary	Polypeptide chains may form α helices or β pleated sheets.	Hydrogen bonds	
(C) Tertiary	Polypeptides fold, forming specific shapes	Hydrogen bonds; disulfide bridges; hydrophobic interactions	
(D) Quaternary	Two or more polypeptides assemble to form larger protein molecules.	Hydrogen bonds; disulfide bridges; hydrophobic interactions; ionic interactions	

Figure 3.7 The Four Levels of Protein Structure Secondary, tertiary, and quaternary structure all arise from the primary structure of the protein.

Q: If a protein is gently heated to break hydrogen bonds, what level(s) of structure will be unaffected, and why?

The primary structure of a protein is its amino acid sequence

The precise sequence of amino acids in a polypeptide chain held together by peptide bonds constitutes the **primary structure** of a protein (see [Figure 3.7A](#)). The backbone of the polypeptide chain consists of the repeating sequence —N—C—C— made up of the N atom from the amino group, the α C atom, and the C atom from the carboxyl group in each amino acid.

primary structure The specific sequence of amino acids in a protein.

The single-letter abbreviations for amino acids (see [Table 3.2](#)) are used to record the amino acid sequence of a protein. Here, for example, are the first 20 amino acids (out of a total of 124) in the protein ribonuclease from a cow:

KETAAAKFERQHMDSSSTSA

The theoretical number of different proteins is enormous. Since there are 20 different amino acids, there could be $20 \times 20 = 400$ distinct dipeptides (two linked amino acids) and $20 \times 20 \times 20 = 8,000$ different tripeptides (three linked amino acids). Imagine this process of multiplying by 20 extended to a protein made up of 100 amino acids (which would be considered a small protein). There could be 20^{100} (that's approximately 10^{130}) such small proteins, each with its own distinctive primary structure. How large is the number 20^{100} ? Physicists tell us there aren't that many electrons in the entire universe!

The sequence of amino acids in the polypeptide chain determines its final shape. The properties associated with each functional group in the side chains of the amino acids (see [Table 3.2](#)) determine how the protein can twist and fold, thus adopting a specific stable structure that distinguishes it from every other protein.

The secondary structure of a protein requires hydrogen bonding

A protein's [secondary structure](#) consists of regular, repeated spatial patterns in different regions of a polypeptide chain. There are two basic types of secondary structure, both determined by hydrogen bonding between the amino acids that make up the primary structure: the α helix and the β pleated sheet.

secondary structure Of a protein, localized regularities of structure, such as the α helix and the β pleated sheet. (Contrast with primary, tertiary, quaternary structure.)

THE ALPHA HELIX

The α (**alpha**) **helix** is a right-handed coil that turns in the same direction as a standard wood screw (see [Figure 3.7B](#) and [Figure 3.8](#)). The R groups extend outward from the peptide backbone of the helix. The coiling results from hydrogen bonds that form between the δ^+ hydrogen of the N—H of one amino acid and the δ^- oxygen of the C=O of another. When this pattern of hydrogen bonding is established repeatedly over a segment of the protein, it stabilizes the coil.

Figure 3.8 Left- and Right-Handed Helices A protein will often have one or more right-handed helices as part of its secondary structure.

THE BETA PLEATED SHEET

A β (**beta**) **pleated sheet** is formed from two or more polypeptide chains that are almost completely extended and aligned. The sheet is stabilized by hydrogen bonds between the N—H groups on one chain and the C=O groups on the other (see [Figure 3.7B](#)). A β pleated sheet may form between separate polypeptide chains or between different regions of a single polypeptide chain that is bent back on itself. The ratcheted, stacked sheets in dragline spider silks (described at the beginning of the chapter and in Investigating Life: Making Spider Silk) are made up of β pleated sheets. Many proteins contain regions of both α helix and β pleated sheet in the same polypeptide chain.

β (beta) pleated sheet A type of protein secondary structure; results from hydrogen bonding between polypeptide regions running antiparallel to each other.

The tertiary structure of a protein is formed by bending and folding

In many proteins, the polypeptide chain is bent at specific sites and then folded back and forth, resulting in the **tertiary structure** of the protein (see [Figure 3.7C](#)). Although α helices and β pleated sheets contribute to the tertiary structure, usually only portions of the macromolecule have these secondary structures, and large regions consist of tertiary structure unique to a particular protein. For example, the proteins found in stretchy spider silks (see the opening story) have repeated amino acid sequences that cause the proteins to fold into spirals. Tertiary structure is a macromolecule's definitive three-dimensional shape, often including a buried interior as well as a surface that is exposed to the environment.

tertiary structure In reference to a protein, the relative locations in three-dimensional space of all the atoms in the molecule. The overall shape of a protein. (Contrast with primary, quaternary, secondary, structures.)

The protein's exposed outer surfaces present functional groups capable of interacting with other molecules in the cell. These molecules might be other macromolecules, including proteins, nucleic acids, carbohydrates, and lipid structures, or smaller chemical substances.

You saw that hydrogen bonding between the N—H and C=O groups within and between chains is responsible for secondary structure. For tertiary structure, the interactions between R groups—the amino acid side chains—and between R groups and the environment are key. Recall the various strong and weak interactions between atoms described in [Key Concept 2.2](#). Here is how these interactions are involved in determining and maintaining tertiary structure:

Covalent disulfide bridges can form between specific cysteine side chains (see [Figure 3.5](#)), holding a folded polypeptide in place.

Hydrogen bonds between side chains also stabilize folds in proteins.

Hydrophobic side chains can aggregate together in the interior of the protein, away from water, folding the polypeptide in the process. Close interactions between the hydrophobic side chains are stabilized by van der Waals forces.

Ionic attractions can form between positively and negatively charged side chains, forming salt bridges between amino acids. Salt bridges can be near the surfaces of polypeptides or buried deep within a protein, away from water. These interactions occur between positively and negatively charged amino acids, for example glutamic acid (which has a negatively charged R group) and arginine (which is positively charged) (see [Table 3.2](#)):

A protein folds into its final shape in a way that maximizes all the interactions noted and minimizes inappropriate interactions, such as two positively charged residues (a term identifying monomers in a polymer) being near one another, or a hydrophobic residue being near water. A complete description of a protein's tertiary structure would specify the location of every atom in the molecule in three-dimensional space relative to all the other atoms. [Figure 3.9](#) shows three ways of modeling the structure of the protein lysozyme. Each way has its uses. The space-filling model might be used to study how other molecules interact with specific sites and R groups on the protein's surface. The stick model emphasizes the sites where bends occur, resulting in folds in the polypeptide chain. The ribbon model, perhaps the most widely used, shows the different types of secondary structure and how they fold into the tertiary structure.

A realistic depiction of lysozyme shows dense packing of its atoms.

(A) Space-filling model

B) Stick model (C) Ribbon model

Figure 3.9 Three Representations of Lysozyme Different molecular representations of a protein emphasize different aspects of its tertiary structure: surface features, sites of bends and folds, or sites where alpha or beta structures predominate. These three representations of lysozyme are similarly oriented.

Q: Can you identify regions of the protein that are hydrophilic? Hydrophobic?

 Media Clip 3.1 **Protein Structures in 3D** www.Life11e.com/mc3.1

Remember that both secondary and tertiary structure derive from primary structure. If a protein is heated slowly and moderately, the heat energy will disrupt only the weak interactions, causing the secondary and tertiary structure to break down. The protein is then said to be **denatured**. A comparison of native (untreated) and denatured proteins shows major differences:

Native proteins are compact; denatured proteins have a larger volume.

Native proteins exist in one, preferred shape; denatured proteins can take many shapes.

Native proteins have hydrogen bonds that stabilize the structure internally; denatured proteins have hydrogen bonds on the exterior, to water.

You can't "unboil" an egg after it has been hard-boiled; the egg proteins are irreversibly denatured. Amazingly, in some cases a protein can return to its normal tertiary structure when it cools, demonstrating that all the information needed to specify the unique shape of a protein is contained in its primary structure. This was first shown (using chemicals instead of heat to denature the protein) by biochemist Christian Anfinsen for the protein ribonuclease ([Figure 3.10](#)).

Figure 3.10A Primary Structure Specifies Tertiary Structure

Original Papers: Anfinsen, C. B., E. Haber, M. Sela and F. White, Jr. 1961. The kinetics of formation of native ribonuclease during oxidation of the reduced polypeptide chain. *Proceedings of the National Academy of Sciences USA* 47: 1,309–1,314.

White, Jr., F. 1961. Regeneration of native secondary and tertiary structures by air oxidation of reduced ribonuclease. *Journal of Biological Chemistry* 236: 1,353–1,360.

Using the protein ribonuclease, Christian Anfinsen showed that proteins spontaneously fold into functionally correct three-dimensional configurations. As long as the primary structure is not disrupted, the information for correct folding (under the right conditions) is retained.

HYPOTHESIS Under controlled conditions that simulate the normal cellular environment, a denatured protein can refold into a functional three-dimensional structure.

METHOD Chemically denature a functional ribonuclease so that only its primary structure (i.e., an unfolded polypeptide chain) remains. Once denaturation is complete, remove the disruptive chemicals.

RESULTS When the disruptive agents are removed, three-dimensional structure is restored and the protein once again is functional.

CONCLUSION In normal cellular conditions, the primary structure of a protein specifies how it folds into a functional, three-dimensional structure.

Figure 3.10B Primary Structure Specifies Tertiary Structure

Original Papers: Anfinsen, C. B. et al. 1961; White, Jr., F. 1961.

After the tertiary structures of proteins were shown to be highly specific, the question arose as to how the order of amino acids determined the three-dimensional structure. The second protein whose structure was determined was ribonuclease A (RNase A). This enzyme was readily available from cow pancreases at slaughterhouses and, because it works in the highly acidic environment of the cow stomach, was stable compared with most proteins and easy to purify. RNase A has 124 amino acids. Among these are eight cysteine residues, which form four disulfide bridges. Were these covalent links between cysteines essential for the three-dimensional structure of RNase A? As outlined in Figure 3.10A, Christian Anfinsen and his colleagues set out to answer this question.

QUESTIONS

1. Initially, the disulfide bonds (S—S) in RNase A were eliminated because the sulfur atoms in cysteine residues were all reduced (—SH). At time zero, reoxidation began; and at various times, the amount of S—S bond re-formation and the activity of the enzyme were measured by chemical methods. The data are shown in **Figure A**.
At what time did disulfide bonds begin to form? At what time did enzyme activity begin to appear? Explain the difference between these times.

2. The three-dimensional structure of RNase A was examined by ultraviolet spectroscopy. In this technique, the protein was exposed to different wavelengths of ultraviolet light (measured in nanometers) and the amount of light absorbed by the protein at each wavelength was measured (E). The results are plotted in **Figure B**.

Look carefully at the plots. What are the differences between the peak absorbances of native (untreated) and reduced (denatured) RNase A? What happened when reduced RNase A was reoxidized (renatured)? What can you conclude about the structure of RNase A from these experiments?

Figure A**Figure B**

A similar **work with the data** exercise may be assigned in **LaunchPad**.

The quaternary structure of a protein consists of subunits

Many functional proteins contain two or more polypeptide chains, called subunits, each of them folded into its own unique tertiary structure. The protein's **quaternary structure** results from the ways in which these subunits bind together and interact (see [Figure 3.7D](#)).

quaternary structure The specific three-dimensional arrangement of protein subunits. (Contrast with primary, secondary, tertiary structure.)

Hemoglobin has four polypeptide chains interacting to form quaternary structure ([Figure 3.11](#)). Hydrophobic interactions, van der Waals forces, hydrogen bonds, and ionic attractions all help hold the four subunits together to form a hemoglobin molecule. However, the weak nature of these forces permits small changes in the quaternary structure to aid the protein's function—which is to carry oxygen in red blood cells. As hemoglobin binds one O_2 molecule, the four subunits shift their relative positions slightly, changing the quaternary structure. Ionic attractions are broken, exposing buried side chains that enhance the binding of additional O_2 molecules. The quaternary structure changes back when hemoglobin releases its O_2 molecules to the cells of the body.

(A) Ribbon model

(B) Space-filling model

Figure 3.11 Quaternary Structure of a Protein Hemoglobin consists of four folded polypeptide subunits that assemble themselves into the quaternary structure represented by the ribbon model (A) and spacefilling model (B). In both graphic representations, each type of subunit is a different color (α subunits are blue and β subunits are green). The heme groups (red) contain iron and are the oxygen-carrying sites.

Shape and surface chemistry contribute to protein function

The shapes of proteins allow specific sites on their exposed surfaces to bind noncovalently to other molecules, which may be large or small. The binding is usually very specific because only certain compatible chemical groups will bind to one another. The specificity of protein binding depends on two general properties of the protein: its shape, and the chemistry of its exposed surface groups.

Shape. When a small molecule collides with and binds to a much larger protein, it is like a baseball being caught by a catcher's mitt: the mitt has a shape that binds to the ball and fits around it. Just as a hockey puck or a ping-pong ball does not fit a baseball catcher's mitt, a given molecule will not bind to a protein unless there is a general "fit" between their three-dimensional shapes.

Chemistry. The exposed R groups on the surface of a protein permit chemical interactions with other substances ([Figure 3.12](#)). Three types of interactions may be involved: ionic, hydrophobic, or hydrogen bonding. Many important functions of proteins involve interactions between surface R groups and other molecules.

Figure 3.12 Noncovalent Interactions between Proteins and Other Molecules Noncovalent interactions (see p. 51) allow a protein (red) to bind tightly to another molecule (green) with specific properties. Noncovalent interactions also allow regions within the same protein to interact with one another.

Q: Why are these interactions sensitive to heat? (Hint: see [Table 2.1](#).)

Environmental conditions affect protein structure

Because they are determined by weak forces, the three-dimensional structures of proteins are influenced by environmental conditions. Conditions that would not break covalent bonds can disrupt the weaker, noncovalent interactions that determine secondary, tertiary, and quaternary structure. Such alterations may affect a protein's shape and thus its function. Various conditions can alter the weak, noncovalent interactions:

Increases in temperature cause more rapid molecular movements and thus can break hydrogen bonds and hydrophobic interactions.

Changes in pH can change the pattern of ionization of exposed carboxyl and amino groups in the R groups of amino acids, thus disrupting the pattern of ionic attractions and repulsions.

High concentrations of polar substances such as urea can disrupt the hydrogen bonding that is crucial to protein structure. Urea was used in the experiment on reversible protein denaturation shown in [Figure 3.10](#).

Nonpolar substances may also disrupt normal protein structure in cases where hydrophobic interactions are essential to maintain the structure.

Protein shapes can change

As we saw in the case of hemoglobin, which undergoes subtle shape changes when it binds oxygen, the shapes of proteins can change as a result of their interactions with other molecules. Proteins can also change shape if they undergo covalent modifications.

Proteins interact with other molecules. Proteins do not exist in isolation. In fact, if a biochemist “goes fishing” with a particular protein, by attaching the protein to a chemical “hook” and inserting it into cells, the protein will often be attached to something else when it is “reeled in.” These molecular interactions are reminiscent of the interactions that make up quaternary structure (see above). If a polypeptide comes into contact with another molecule, R groups on its surface may form weak interactions (e.g., hydrophobic, van der Waals) with groups on the surface of the other molecule. This may disrupt some of the interactions between R groups within the polypeptide, causing it to undergo a change in shape ([Figure 3.13A](#)). You will see many instances of this in the coming chapters.

Figure 3.13 Protein Structure Can Change Proteins can change their tertiary structure when they bind to other molecules (A) or are modified chemically (B).

Proteins undergo ***covalent modifications**. After it is made, the structure of a protein can be modified by the covalent bonding of a chemical group to the side chain of one or more of its amino acids. The chemical modification of just one amino acid can alter the shape and function of a protein. An example is the addition of a charged phosphate group to a relatively nonpolar R group. This can cause the amino acid to become more hydrophilic and to move to the outer surface of the protein, altering the shape of the protein in the region near the amino acid ([Figure 3.13B](#)).

Molecular chaperones help shape proteins

Within a living cell, a polypeptide chain is sometimes in danger of binding the wrong substance. There are two major situations when this can occur:

- . *Just after a protein is made.* When a protein has not yet folded completely, it can present a surface that binds the wrong molecule.
- . *Following denaturation.* Certain conditions, such as moderate heat, can cause some proteins in a living cell to denature without killing the organism. Before the protein can refold, it may present a surface that binds the wrong molecule. In these cases, the inappropriate binding may be irreversible.

Many cells have a special class of proteins, called **chaperones**, that protect the three-dimensional structures of other proteins. They bind to their partner proteins just as they are being made and also when they become denatured. Like the chaperones at a high school dance, chaperone proteins prevent inappropriate interactions and enhance appropriate ones. Typically, a chaperone protein has a cage-like structure that pulls in a polypeptide, causes it to fold into the correct shape, and then releases it ([Figure 3.14](#)). Tumors make chaperone proteins, possibly to stabilize proteins important in the cancer process, and so chaperone-inhibiting drugs are being designed for use in chemotherapy. In some clinical situations, treatment with these inhibitors results in the inappropriate folding of proteins in tumor cells, causing the tumors to stop growing.

chaperone A protein that guards other proteins by counteracting molecular interactions that threaten their three-dimensional structure.

Figure 3.14 Molecular Chaperones Protect Proteins from Inappropriate Binding

Chaperone proteins surround new or denatured proteins and prevent them from binding to the wrong substances. Heat shock proteins such as HSP60, shown here, make up one class of chaperone proteins.

Q: Why are heat shock proteins important for a cell?

3.2 recap

Proteins are polymers of amino acids. The sequence of amino acids in a protein is its primary structure. Secondary, tertiary, and quaternary structures arise through interactions among the amino acids. A protein's three-dimensional shape and exposed chemical groups establish its binding specificity for other substances.

learning outcomes

You should be able to:

- Predict how a protein's tertiary structure will be affected by a change in an amino acid in its primary structure.
- Analyze data to determine why an amino acid change in a protein leads to a change in the protein's shape.
- Predict the effects of various environmental factors on a protein's structure.

1. Suppose that, in a given protein, one lysine is replaced by aspartic acid (see [Table 3.2](#)). Does this change occur in the primary structure or in the secondary structure? How might it result in a change in tertiary structure? In quaternary structure?
2. A single amino acid change in a protein can change its shape. For example, the amino acid glycine may normally reside at a certain position in a protein. If glycine is replaced with either glutamic acid or arginine, the protein shape near that amino acid changes significantly. There are two possible explanations for this:
 - a. A small amino acid at that position in the polypeptide is necessary for normal shape.
 - b. An uncharged amino acid is necessary for normal shape.Further amino acid substitutions are done to distinguish between these possibilities. Replacing glycine with serine or alanine results in normal shape, but replacing glycine with valine changes the shape. Which of the two possible explanations is supported by the observations? Explain your answer.
3. Human hair is composed of the protein keratin. At the hair salon, two techniques are used to modify the three-dimensional shape of hair. Styling involves heat, and a perm involves cleaving and re-forming disulfide bonds. How would you investigate these phenomena in terms of protein structure?

***connect the concepts** Covalent modifications of proteins with subsequent changes in shape and function underlie many biological processes, ranging from signaling within the cell (see [Key Concept 7.3](#)) to the action of plant hormones on growth (see [Key Concept 37.2](#)).

3.3 Simple Sugars Are the Basic Structural Unit of Carbohydrates

Carbohydrates make up a large group of molecules that all have similar atomic compositions but differ greatly in size, chemical properties, and biological functions. Carbohydrates usually have the general formula $(C_1H_2O_1)_n$, (n stands for a number), which makes them appear as “hydrates of carbon” (a hydrate refers to water), hence their name. However, carbohydrates are not really “hydrates” because the water molecules are not intact. Rather, the linked carbon atoms are bonded with hydrogen atoms ($—H$) and hydroxyl groups ($—OH$), the components of water.

carbohydrates Organic compounds containing carbon, hydrogen, and oxygen in the ratio 1:2:1 (i.e., with the general formula $C_nH_{2n}O_n$). Common examples are sugars, starch, and cellulose.

Carbohydrates have four major biochemical roles:

- . They are a source of stored energy that can be released in a form usable by organisms.
- . They are used to transport stored energy within complex organisms.
- . They serve as carbon skeletons that can be rearranged to form new molecules.
- . They form extracellular assemblies such as cell walls that provide structure to organisms.

Some carbohydrates are relatively small, with molecular weights of less than 100. Others are true macromolecules, with molecular weights in the hundreds of thousands.

focus your learning

Carbohydrates function primarily in storing and transporting chemical energy and as sources of carbon for building new macromolecules.

Polysaccharides of glucose all provide energy storage and structural functions but vary in branching patterns and type of glycosidic linkages between glucose units.

There are four categories of biologically important carbohydrate defined by the number of monomers:

- . **Monosaccharides** (*mono*, “one,” + *saccharide*, “sugar”), such as glucose, are simple sugars. They are the monomers from which the larger carbohydrates are constructed.
- . **Disaccharides** (*di*, “two”) consist of two monosaccharides linked together by covalent bonds. The most familiar is sucrose, which is made up of covalently bonded glucose and fructose molecules.
- . **Oligosaccharides** (*oligo*, “several”) are made up of several (3–20) monosaccharides.
- . **Polysaccharides** (*poly*, “many”), such as starch, glycogen, and cellulose, are polymers made up of hundreds or thousands of monosaccharides.

monosaccharide A simple sugar. Oligosaccharides and polysaccharides are made up of monosaccharides.

disaccharide A carbohydrate made up of two monosaccharides (simple sugars).

oligosaccharide A polymer containing a small number of monosaccharides.

polysaccharide A macromolecule composed of many monosaccharides (simple sugars). Common examples are cellulose and starch.

Monosaccharides are simple sugars

All living cells contain the monosaccharide **glucose**; it is the “blood sugar” used to store and transport energy in humans. Cells use glucose as an energy source, breaking it down through a series of reactions that converts stored energy to more usable chemical energy and produce carbon dioxide; this is a cellular form of the combustion reaction you saw in [Key Concept 2.3](#).

glucose [Gk. *gleukos*: sugar, sweet wine] The most common monosaccharide; the monomer of the polysaccharides starch, glycogen, and cellulose.

Glucose exists in straight chains and in ring forms. The ring forms predominate in virtually all biological circumstances because they are more stable in water. There are two versions of the glucose ring, called α - and β -glucose, which differ only in the orientation of the —H and —OH groups attached to carbon 1 ([Figure 3.15](#)). The α and β forms interconvert and exist in equilibrium when dissolved in water.

Figure 3.15 From One Form of Glucose to the Other All glucose molecules have the formula $C_6H_{12}O_6$, but their structures vary. When dissolved in water, the α and β “ring” forms of glucose interconvert. The convention used here for numbering the carbon atoms is standard in biochemistry.

Activity 3.3 Forms of Glucose www.Life11e.com/ac3.3

Different monosaccharides contain different numbers of carbons. Some monosaccharides are structural isomers, with the same kinds and numbers of atoms but in different arrangements ([Figure 3.16](#)). Such seemingly small structural changes can significantly alter their properties. Most of the monosaccharides in living systems belong to the D (right-handed) series of optical isomers.

Glyceraldehyde is the smallest monosaccharide and exists only as the straight-chain form.

Three-carbon sugar

Ribose and deoxyribose each have five carbons, but different chemical properties and biological roles.

Five-carbon sugars (pentoses)

These hexoses are structural isomers. All have the formula $C_6H_{12}O_6$, but each has distinct biochemical properties.

Six-carbon sugars (hexoses)

Figure 3.16 Monosaccharides Are Simple Sugars Monosaccharides are made up of varying numbers of carbons. Some hexoses are structural isomers that have the same kind and number of atoms, but the atoms are arranged differently. Fructose, for example, is a hexose but forms a five-membered ring like the pentoses.

Pentoses (*pente*, “five”) are five-carbon sugars. Two pentoses are of particular biological importance: the backbones of the nucleic acids RNA and DNA contain ribose and deoxyribose, respectively (see [Key Concept 4.1](#)). These two pentoses are not isomers of each other; rather, one oxygen atom is missing from carbon 2 in deoxyribose (*de*-, “absent”). The absence of this oxygen atom is an important distinction between RNA and DNA

The **hexoses** (*hex*, “six”) shown in [Figures 3.15](#) and [3.16](#) are a group of structural isomers with the formula $C_6H_{12}O_6$. Common hexoses are glucose, fructose (so named because it was first found in fruits), mannose, and galactose.

pentose [Gk. *penta*: five] A sugar containing five carbon atoms.

hexose [Gk. *hex*: six] A sugar containing six carbon atoms.

Glycosidic linkages bond monosaccharides

The disaccharides, oligosaccharides, and polysaccharides are all constructed from monosaccharides that are covalently bonded together by condensation reactions that form **glycosidic linkages** (Figure 3.17). A single glycosidic linkage between two monosaccharides forms a disaccharide. For example, sucrose—common table sugar (the real stuff, not artificial sweetener) in the human diet and the major disaccharide in plants—is formed from a glucose and a fructose molecule.

glycosidic linkage Bond between carbohydrate (sugar) molecules through an intervening oxygen atom (–O–).

Figure 3.17 Disaccharides Form by Glycosidic Linkages Glycosidic linkages between two monosaccharides can create many different disaccharides. The particular disaccharide formed depends on which monosaccharides are linked, on the site of linkage (i.e., which carbon atoms are involved), and on the form (α or β) of the linkage.

The disaccharides maltose and cellobiose are made from two glucose molecules (see Figure 3.17). Maltose and cellobiose are structural isomers, both having the formula $\text{C}_{12}\text{H}_{22}\text{O}_{11}$. However, they have different chemical properties and are recognized by different ***enzymes** in biological tissues. For example, maltose can be hydrolyzed into its monosaccharides in the human body, whereas cellobiose cannot.

Oligosaccharides contain several monosaccharides bound by glycosidic linkages at various sites. Many oligosaccharides have additional functional groups, which give them special properties. Oligosaccharides are often covalently bonded to proteins and lipids on the outer cell surface, where they serve as recognition signals. The different human blood groups (e.g., the ABO blood types) get their specificities from oligosaccharide chains.

Polysaccharides store energy and provide structural materials

Polysaccharides are large (sometimes gigantic) polymers of monosaccharides connected by glycosidic linkages (Figure 3.18). In contrast to polypeptides, polysaccharides are not

necessarily linear chains of monomers. Each monomer unit has several sites that are capable of forming glycosidic linkages, and thus branched molecules are possible.

(A) Molecular structure

(B) Macromolecular structure

(C) Polysaccharides in cells

Figure 3.18 Representative Polysaccharides Cellulose, starch, and glycogen have different levels of branching and compaction of the polysaccharides.

STARCH

Starches comprise a family of large molecules with similar structures. While all starches are polysaccharides of glucose with α -glycosidic linkages (α -1,4 and α -1,6 glycosidic bonds; see [Figure 3.18A](#)), the different starches can be distinguished by the amount of branching that occurs at carbons 1 and 6 (see [Figure 3.18B](#)). Starch is the principal energy storage compound of plants. Some plant starches, such as amylose, are unbranched; others are moderately branched (for example, amylopectin). Starch readily binds water; if you're a cook you know this. However, when water is removed, hydrogen bonds form between the unbranched polysaccharide chains, which then aggregate. Large starch aggregates called starch grains can be observed in the storage tissues of plant seeds (see [Figure 3.18C](#)). These aggregates are broken up when starch is heated, breaking the hydrogen bonds. The starch becomes less solid and crystalline and water is absorbed, making the starch even more amorphous. This is what

happens in baking with wheat flour, and is what gives bread its texture. Next time you eat some bread, think of hydrogen bonds!

starch [O.E. *stearc*: stiff] A polymer of glucose; used by plants to store energy.

GLYCOGEN

Glycogen is a water-insoluble, highly branched polymer of glucose. It is used to store glucose in the liver and muscles and is thus an energy storage compound for animals, as starch is for plants. Both glycogen and starch are readily hydrolyzed into glucose monomers, which in turn can be broken down to liberate their stored energy.

glycogen (gly' ko jen) [Gk. *glyk*: sweet] An energy storage polysaccharide found in animals and fungi; a branched-chain polymer of glucose, similar to starch.

But if it is glucose that is needed for fuel, why store it in the form of glycogen? The reason is that 1,000 glucose molecules would exert 1,000 times the osmotic pressure of a single glycogen molecule, causing water to enter cells where glucose is stored (see [Key Concept 6.3](#)). If it were not for polysaccharides, many organisms would expend a lot of energy expelling excess water from their cells.

CELLULOSE

As the predominant component of plant cell walls, **cellulose** is by far the most abundant organic compound on Earth. Like starch and glycogen, cellulose is a polysaccharide of glucose, but its individual monosaccharides are connected by β - rather than by α -glycosidic linkages. Starch is easily degraded by the actions of chemicals or enzymes. Cellulose, however, is chemically more stable because of its β -glycosidic linkages.

cellulose (sell' you lowss) A straight-chain polymer of glucose molecules, used by plants as a structural supporting material.

Thus whereas starch is easily broken down to supply glucose for energy-producing reactions, cellulose is an excellent structural material that can withstand harsh environmental conditions without substantial change.

Chemically modified carbohydrates contain additional functional groups

Some carbohydrates are chemically modified by the addition of functional groups such as phosphate, amino, or *N*-acetyl groups ([Figure 3.19](#)). For example, a phosphate group may be added to one or more of the —OH sites (see [Figure 3.19A](#)). Some of the resulting sugar phosphates, such as fructose 1,6-bisphosphate, are important intermediates in cellular energy reactions, which you'll see in [Chapter 9](#).

Fructose 1,6-bisphosphate is involved in the reactions that liberate energy from glucose. (The numbers in its name refer to the carbon sites of phosphate bonding; *bis*- indicates that two phosphates are present.)

Fructose 1,6-bisphosphate

(A) Sugar phosphate

The monosaccharides glucosamine and galactosamine are amino sugars with an amino group in place of a hydroxyl group.

Galactosamine is an important component of cartilage, a connective tissue in vertebrates.

(B) Amino sugars

Chitin is a polymer of *N*-acetylglucosamine; *N*-acetyl groups provide additional sites for hydrogen bonding between the polymers.

The external skeletons of insects are made up of chitin.

(C) Chitin

Figure 3.19 Chemically Modified Carbohydrates Added functional groups can modify the form and properties of a carbohydrate.

When an amino group (NH_2) is substituted for an —OH group, amino sugars, such as glucosamine and galactosamine, are produced (see [Figure 3.19B](#)). These compounds are important in the extracellular matrix (see [Key Concept 5.4](#)), where they form parts of glycoproteins, which are molecules involved in keeping tissues together. Galactosamine is a major component of cartilage, the material that forms caps on the ends of bones and stiffens the ears and nose. A derivative of glucosamine is present in the polymer chitin (see [Figure 3.19C](#)), the principal structural polysaccharide in the external skeletons of insects and many crustaceans (such as crabs and lobsters), and a component of the cell walls of fungi.

3.3 recap

Carbohydrates are composed of carbon, hydrogen, and oxygen and have the general formula $(\text{C}_1\text{H}_2\text{O}_1)_n$. They provide energy and structure to cells and are precursors of numerous important biological molecules. Monosaccharide monomers can be connected by

glycosidic linkages to form disaccharides, oligosaccharides, and polysaccharides.

learning outcomes

You should be able to:

- Identify the primary functions of carbohydrates in living organisms.
 - Explain why polysaccharides are useful structures for energy storage.
 - Use the chemical structures of polysaccharides to explain their properties.
-

1. What qualities of the polysaccharides starch and glycogen make them useful for energy storage?
 2. After looking at the cellulose molecule in [Figure 3.18A](#), can you see why a large number of hydrogen bonds are present in the linear structure of cellulose shown in [Figure 3.18B](#)? Why is this structure so strong?
-

You have seen how amino acid monomers form protein polymers and how sugar monomers form the polymers of carbohydrates. Now we will look at the lipids, which are unique among the four classes of large biological molecules in that they are not, strictly speaking, polymers.

***connect the concepts** Enzymes are an important class of proteins that may change shape when they come into contact with a reactant in a biochemical reaction. Each enzyme is specific for the reactant it binds. See [Key Concept 8.4](#).

3.4 Lipids Are Defined by Their Solubility Rather Than by Chemical Structure

Lipids—colloquially called fats—are hydrocarbons that are insoluble in water because of their many nonpolar covalent bonds. As you saw in [Key Concept 2.2](#), nonpolar hydrocarbon molecules are hydrophobic and preferentially aggregate together, away from water, which is polar. When nonpolar hydrocarbons are sufficiently close to one another, weak but additive van der Waals forces help hold them together. The huge macromolecular aggregations that can form are not polymers in a strict chemical sense, because the individual lipid molecules are not covalently bonded. With this understanding, it is still useful to consider aggregations of individual lipids as a different sort of polymer.

lipid (lip' id) [Gk. *lipos*: fat] Nonpolar, hydrophobic molecules that include fats, oils, waxes, steroids, and the phospholipids that make up biological membranes.

focus your learning

Triglycerides are simple lipids composed of glycerol bonded to three fatty acids via ester linkages.

Because phospholipids are amphipathic, they are able to aggregate to form phospholipid bilayers, which are useful in creating membrane structures.

Carotenoids, steroids, certain vitamins, and waxes are classified as lipids and have a variety of functions, depending on their chemical structures.

There are several different types of lipids, and they play a number of roles in living organisms:

Fats and oils store energy.

Phospholipids play important structural roles in cell membranes.

Carotenoids and chlorophylls help plants capture light energy.

Steroids and modified fatty acids play regulatory roles as hormones and vitamins.

Fat in animal bodies serves as thermal insulation.

A lipid coating around nerves provides electrical insulation.

Oil or wax on the surfaces of skin, fur, feathers, and leaves repels water and prevents excessive evaporation of water from terrestrial animals and plants.

Fats and oils are triglycerides

Chemically, fats and oils are **triglycerides**, also known as simple lipids. Triglycerides that are solid at room temperature (around 20°C) are called **fats**; those that are liquid at room temperature are called **oils**. Triglycerides are composed of two types of building blocks: fatty acids and glycerol. **Glycerol** is a small molecule with three hydroxyl (—OH) groups (thus it is an alcohol). A **fatty acid** is made up of a long nonpolar hydrocarbon chain and an acidic polar carboxyl group (—COOH). These chains are very hydrophobic because of their abundant C—H

and C—C bonds, which have similar [*electronegativity](#) values and are therefore nonpolar.

triglyceride A simple lipid in which three fatty acids are combined with one molecule of glycerol.

fat (1) A triglyceride that is solid at room temperature. (Contrast with oil.) (2) Adipose tissue, one type of connective tissue. (See brown fat.)

oil A triglyceride that is liquid at room temperature. (Contrast with fat.)

glycerol (gliss' er ole) A three-carbon alcohol with three hydroxyl groups; a component of phospholipids and triglycerides.

fatty acid A molecule made up of a long nonpolar hydrocarbon chain and a polar carboxyl group. Found in many lipids.

A triglyceride contains three fatty acid molecules and one molecule of glycerol. Making a triglyceride involves three condensation (dehydration) reactions. In each reaction, the carboxyl group of a fatty acid bonds with a hydroxyl group of glycerol, resulting in a covalent bond called an [ester linkage](#) and the release of a water molecule ([Figure 3.20](#)). The three fatty acids in a triglyceride molecule need not all have the same hydrocarbon chain length or structure; some may be saturated fatty acids, whereas others may be unsaturated:

ester linkage A condensation (water-releasing) reaction in which the carboxyl group of a fatty acid reacts with the hydroxyl group of an alcohol. Lipids, including most membrane lipids, are formed in this way. (Contrast with ether linkage.)

Figure 3.20 Synthesis of a Triglyceride In living things, the reaction that forms a triglyceride is more complex, but the end result is the same as shown here.

In [saturated fatty acids](#), all the bonds between the carbon atoms in the hydrocarbon chain are single bonds—there are no double bonds. That is, all the bonds are saturated with hydrogen atoms ([Figure 3.21A](#)). These fatty acid molecules are relatively straight, and they pack together tightly, like pencils in a box.

saturated fatty acid A fatty acid in which all the bonds between carbon atoms in the hydrocarbon chain are single bonds—that is, all the bonds are saturated with hydrogen atoms. (Contrast with unsaturated fatty acid.)

(A) Palmitic acid

(B) Linoleic acid

Figure 3.21 Saturated and Unsaturated Fatty Acids (A) The straight hydrocarbon chain of a saturated fatty acid allows the molecule to pack tightly with other, similar molecules. (B) In unsaturated fatty acids, kinks in the chain prevent close packing. The color convention in the models shown here (gray, H; red, O; black, C) is commonly used.

In **unsaturated fatty acids**, the hydrocarbon chain contains one or more double bonds. Linoleic acid is an example of a polyunsaturated fatty acid that has two double bonds near the middle of the hydrocarbon chain, causing kinks in the molecule (**Figure 3.21B**). Such kinks prevent the unsaturated fat molecules from packing together tightly.

unsaturated fatty acid A fatty acid whose hydrocarbon chain contains one or more double bonds. (Contrast with saturated fatty acid.)

The kinks in fatty acid molecules are important in determining the fluidity and melting points of lipids. The triglycerides of animal fats tend to have many long-chain saturated fatty acids packed tightly together; these fats are usually solids at room temperature and have high melting points. The triglycerides of plants, such as corn oil, tend to have short or unsaturated fatty acids. Because of their kinks, these fatty acids pack together poorly and have low melting points, and these triglycerides are usually liquids at room temperature.

Fatty acids are excellent storehouses for chemical energy. As you will see in **Chapter 9**, when the C—H bond is broken, it releases significant energy that an organism can use for its own purposes, such as movement or building up other complex molecules.

Phospholipids form biological membranes

We have mentioned the hydrophobic nature of the many C—C and C—H bonds in fatty acids. But what about the carboxyl functional group at the end of the molecule? When it ionizes and forms COO^- , it is strongly hydrophilic. So a fatty acid is a molecule with a hydrophilic end and a long hydrophobic “tail.” It has two opposing chemical properties—part hydrophobic and part hydrophilic; the technical term for this is **amphipathic**.

amphipathic (am' fi path' ic) [Gk. *amphi*: both + *pathos*: emotion] Of a molecule, having both hydrophilic and hydrophobic regions.

Like triglycerides, **phospholipids** contain fatty acids bound to glycerol by ester linkages. In phospholipids, however, any one of several phosphate-containing compounds replaces the first or third fatty acid, giving phospholipids amphipathic properties (**Figure 3.22A**). The phosphate functional group has a negative electric charge, so this portion of the molecule is hydrophilic, attracting polar water molecules. But the two fatty acids are hydrophobic, so they tend to avoid water and aggregate together or with other hydrophobic substances.

phospholipid A lipid containing a phosphate group; an important constituent of cellular membranes. (See lipid.)

Figure 3.22 Phospholipids (A) Phosphatidylcholine (lecithin) demonstrates the structure of a phospholipid molecule. In other phospholipids, the amino acid serine, the sugar alcohol inositol, or other compounds replace choline. (B) In an aqueous environment, hydrophobic interactions bring the "tails" of phospholipids together in the interior of a bilayer. The hydrophilic "heads" face outward on both sides of the bilayer, where they interact with the surrounding water molecules.

In an aqueous environment, phospholipids line up in such a way that the nonpolar, hydrophobic "tails" pack tightly together and the phosphate-containing "heads" face outward, where they interact with water. The phospholipids can form a **bilayer**: a sheet two molecules thick, with water excluded from the core (**Figure 3.22B**). Biological membranes have this kind of **phospholipid bilayer** structure, and we will devote **Chapter 6** to their biological functions.

bilayer A structure that is two layers in thickness. In biology, most often refers to the phospholipid bilayer of membranes. (See phospholipid bilayer.)

phospholipid bilayer The basic structural unit of biological membranes; a sheet of phospholipids two molecules thick in which the phospholipids are lined up with their hydrophobic "tails" packed tightly together and their hydrophilic, phosphate-containing "heads" facing outward. Also called lipid bilayer.

Some lipids have roles in energy conversion, regulation, and protection

In the paragraphs above we focused on triglycerides and phospholipids—lipids that are involved in energy storage and cell structure. However, there are other nonpolar and amphipathic lipids that have different structures and roles.

CAROTENOIDS

The carotenoids are a family of light-absorbing pigments found in plants and animals. Beta-

carotene (β -carotene) is one of the pigments that traps light energy in leaves during photosynthesis. In humans, a molecule of β -carotene can be broken down into two vitamin A molecules. Vitamin A is used to make the pigment *cis*-retinal, which is required for vision.

Carotenoids are responsible for the colors of carrots, tomatoes, pumpkins, egg yolks, and butter. The brilliant yellows and oranges of autumn leaves are also from carotenoids.

STEROIDS

The steroids are a family of organic compounds whose multiple rings are linked through shared carbons. The steroid cholesterol is an important constituent of membranes, helping maintain membrane integrity (see [Key Concept 6.1](#)).

Other steroids function as hormones: chemical signals that carry messages from one part of the body to another (see [Chapter 40](#)). Cholesterol is synthesized in the liver and is the starting material for making steroid hormones such as testosterone and estrogen.

VITAMINS

Vitamins are small molecules that are not synthesized by the human body or in some cases are synthesized in inadequate amounts and so must be acquired from the diet (see [Chapter 50](#)). For example, vitamin A is formed from the β -carotene found in green and yellow vegetables (see above). In humans, a deficiency of vitamin A leads to dry skin, eyes, and internal body surfaces, retarded growth and development, and night blindness, which is a diagnostic symptom for the deficiency. You'll see in [Chapter 18](#) how plant biologists are producing crops that contain more vitamin A to alleviate this condition. Vitamins D, E, and K are also lipids.

WAXES

Birds and mammals have glands in their skins that secrete waxy coatings onto their hair or feathers. These coatings repel water and help keep the hair and feathers pliable. The shiny leaves of plants such as holly, familiar during winter holidays, also have waxy coatings. Waxy coatings on plants can help them retain water and exclude pathogens. Bees make their honeycombs out of wax. Waxes are substances that are hydrophobic and plastic, or malleable,

at room temperature. Each wax molecule consists of a saturated, long-chain fatty acid and a saturated, long-chain alcohol joined by an ester linkage. The result is a very long molecule with 40–60 CH_2 groups.

3.4 recap

Lipids include both hydrophobic and amphipathic molecules that are largely composed of carbon and hydrogen. They are important in energy storage, light absorption, intercellular communication, and biological structures. A phospholipid is composed of two hydrophobic fatty acids linked to glycerol and a hydrophilic phosphate group. Cell membranes contain phospholipid bilayers.

learning outcomes

You should be able to:

- Compare and contrast triglycerides in fats and oils.
- Describe how the polar and nonpolar natures of phospholipids result in the formation of a membrane bilayer.
- Explain why carotenoids, steroids, certain vitamins, and waxes are classified as lipids.

1. If phospholipids were placed in a nonpolar solvent, would a membrane-type bilayer structure form? Explain your answer, using a diagram.
2. What is the difference between fats and oils?
3. Why are steroids and some vitamins classified as lipids?

In this chapter we discussed three of the classes of macromolecules that are characteristic of living organisms. All organisms are made up of these three types of macromolecules, a fact that shows the wonderful biochemical unity of life. This unity in turns implies that all life has a common origin (see [Key Concept 1.1](#)). Essential to this origin was a fourth class of macromolecule, the nucleic acids. In the next chapter we will turn to the related topics of nucleic acids and the origin of life.

investigatinglife

What are practical uses for spider silk?

Spider silk protein has many glycine and alanine residues, which are hydrophobic and cause the protein to fold into a fibrous shape. More than 1,000 individual polypeptide chains hydrogen bond and hydrophobically interact with one another to form long silk fibers. Because of the strength arising from its protein structure, spider silk is much desired for human uses. Using genetic engineering, biologists have been able to harvest composite silk fibers produced by silkworms in industrial quantities. Now that this composite silk-worm–spider silk is available, numerous applications (functions related to structure) can be contemplated. For example, a recent study compared surgical sutures made from spider silk with widely used sutures made from synthetic fibers to hold together injured tendons. The spider silk sutures were far superior, holding their strength over many cycles of tendon movement during healing. Another application on the horizon is bulletproof vests: the energy required to break a spider silk filament is at least 100 times greater than the energy of a typical bullet in impact.

Future directions

Perhaps the most widespread use for spider silk may be in textiles. By definition, textiles are flexible materials made of natural or artificial fibers (threads) that are woven together. The clothes you are wearing are textiles, perhaps made of cotton fibers (made up of cellulose) or polyester fibers (an artificial polymer) or a combination. Of course, silk fibers from silkworms have a long history in textiles, particularly in Asia. The addition of spider silk fibers, or combined spider–silkworm silk to existing textiles, holds great promise to increase the strength and in some cases the flexibility of the textile.

▶ 3.1 Macromolecules Characterize Living Things

See [Animation 3.1](#)

- **Macromolecules** are **polymers** constructed by the formation of covalent bonds between smaller molecules called **monomers**. Macromolecules in living organisms include polysaccharides, proteins, and nucleic acids. Organizationally, large lipid structures may also be considered like macromolecules.

macromolecule A giant (molecular weight > 1,000) polymeric molecule. The macromolecules are the proteins, polysaccharides, and nucleic acids.

polymer [Gk. *poly*: many + *meros*: unit] A large molecule made up of similar or identical subunits called monomers. (Contrast with monomer.)

monomer [Gk. *mono*: one + *meros*: unit] A small molecule, two or more of which can be combined to form oligomers (consisting of a few monomers) or polymers (consisting of many monomers).

- **Functional groups** are small groups of atoms that are consistently found together in a variety of different macromolecules. Functional groups have particular chemical properties that they confer on any larger molecule of which they are a part. !!**Review Figure 3.1, Activity 3.1**

functional group (1) A characteristic combination of atoms that contributes specific properties (such as charge or polarity) when attached to larger molecules (e.g., carboxyl group, amino group). (2) A group of species that function in similar ways, whether or not they use the same resources. (Compare with guild.)

- **Structural, *cis-trans*, and optical isomers** have the same kinds and numbers of atoms but differ in their structures and properties. **Review Figure 3.2**

optical isomers Two molecular isomers that are mirror images of each other.

- The many functions of macromolecules are directly related to their three-dimensional shapes, which in turn result from the sequences and chemical properties of their monomers.
- Monomers are joined by **condensation reactions**, which release a molecule of water for each bond formed. **Hydrolysis reactions** use water to break polymers into monomers. **Review Figure 3.4**

condensation reaction A chemical reaction in which two molecules become connected by a covalent bond and a molecule of water is released ($AH + BOH \rightarrow AB + H_2O$.) (Contrast with hydrolysis reaction.)

hydrolysis reaction (high drol' uh sis) [Gk. *hydro*: water + *lysis*: break apart] A chemical reaction that breaks a bond by inserting the components of water ($AB + H_2O \rightarrow AH + BOH$). (Contrast with condensation reaction.)

▶ 3.2 Function of a Protein Depends on Its Three-Dimensional Structure

- The functions of **proteins** include support, protection (e.g., skin surface), catalysis, transport, defense, regulation, movement, signaling, and storage. **Review Table 3.1**

protein (pro' teen) [Gk. *protos*: first] Long-chain polymer of amino acids with twenty different common side chains. Occurs with its polymer chain extended in fibrous proteins, or coiled into a compact macromolecule in enzymes and other globular proteins. The component amino acids are encoded in the triplets of messenger RNA, and proteins are the products of genes.

- Proteins consist of one or more **polypeptide chains**, which are polymers of **amino acids**. Four atoms or groups are attached to a central carbon atom: a hydrogen atom, an amino group, a carboxyl group, and a variable R group. The particular properties of each amino acid depend on its **side chain**, or **R group**, which may be charged, polar, or hydrophobic. **Review Table 3.2, Activity 3.2**

polypeptide A large molecule made up of many amino acids joined by peptide linkages. Large polypeptides are called proteins.

amino acid An organic compound containing both NH_2 and $COOH$ groups. Proteins are polymers of amino acids.

side chain See R group.

R group The distinguishing group of atoms of a particular amino acid; also known as a side chain.

- Peptide linkages**, also called peptide bonds, covalently link amino acids into polypeptide chains. These bonds form by condensation reactions between the carboxyl and amino groups. **Review Figure 3.6**

peptide linkage The bond between amino acids in a protein; formed between a carboxyl group and amino group ($-CO-NH-$) with the loss of water molecules.

- The **primary structure** of a protein is the sequence of amino acids in the chain. This chain is folded into a **secondary structure**, which in different parts of the protein may form an **α helix** or a **β pleated sheet**. **Review Focus: Key Figure 3.7A–C**

primary structure The specific sequence of amino acids in a protein.

secondary structure Of a protein, localized regularities of structure, such as the α helix and the β pleated sheet. (Contrast with primary, tertiary, quaternary structure.)

α (alpha) helix A prevalent type of secondary protein structure; a right-handed spiral.

- Disulfide bridges** and noncovalent interactions between amino acids cause polypeptide chains to fold into three-dimensional **tertiary structures**. These bridges as well as noncovalent interactions allow multiple polypeptide chains to form **quaternary**

structures. Review Figure Focus: Key Figure 3.7C and D

disulfide bridge The covalent bond between two sulfur atoms (—S—S—) linking two molecules or remote parts of the same molecule.

tertiary structure In reference to a protein, the relative locations in three-dimensional space of all the atoms in the molecule. The overall shape of a protein. (Contrast with primary, quaternary, secondary, structures.)

quaternary structure The specific three-dimensional arrangement of protein subunits. (Contrast with primary, secondary, tertiary structure.)

- Heat, alterations in pH, and certain chemicals can all result in a protein becoming **denatured**. This involves the loss of tertiary and/or secondary structure as well as biological function. **Review Figure 3.10**
- The specific shape and structure of a protein allow it to bind non-covalently to other molecules. In addition, amino acids may be modified by the covalent bonding of chemical groups to their side chains. Such binding may result in a protein changing its shape. **Review Figures 3.12, 3.13**
- **Chaperone proteins** enhance correct protein folding and prevent inappropriate binding to other molecules. **Review Figure 3.14**

chaperone A protein that guards other proteins by counteracting molecular interactions that threaten their three-dimensional structure.

▶ 3.3 Simple Sugars Are the Basic Structural Unit of Carbohydrates

- **Carbohydrates** contain carbon bonded to hydrogen and oxygen atoms and have the general formula $(C_1H_2O_1)_n$.

carbohydrates Organic compounds containing carbon, hydrogen, and oxygen in the ratio 1:2:1 (i.e., with the general formula $C_nH_{2n}O_n$). Common examples are sugars, starch, and cellulose.

- **Monosaccharides** are the monomers that make up larger carbohydrates. **Hexoses** such as **glucose** are six-carbon monosaccharides; **pentoses** have five carbons. **!!Review Figure 3.16, Activity 3.3**

monosaccharide A simple sugar. Oligosaccharides and polysaccharides are made up of monosaccharides.

hexose [Gk. *hex*: six] A sugar containing six carbon atoms.

glucose [Gk. *gleukos*: sugar, sweet wine] The most common monosaccharide; the monomer of the polysaccharides starch, glycogen, and cellulose.

pentose [Gk. *penta*: five] A sugar containing five carbon atoms.

- **Glycosidic linkages**, which have either an α or a β orientation in space, are covalent bonds between monosaccharides. Two linked monosaccharides are called a **disaccharide**; larger units are **oligosaccharides** and **polysaccharides**. **Review Figure 3.17**

glycosidic linkage Bond between carbohydrate (sugar) molecules through an intervening oxygen atom (–O–).

disaccharide A carbohydrate made up of two monosaccharides (simple sugars).

oligosaccharide A polymer containing a small number of monosaccharides.

polysaccharide A macromolecule composed of many monosaccharides (simple sugars). Common examples are cellulose and starch.

- **Starch** is a polymer of glucose that stores energy in plants, and **glycogen** is an analogous polymer in animals. They can be easily broken down to release stored energy. **Review Figure 3.18**

starch [O.E. *stearc*: stiff] A polymer of glucose; used by plants to store energy.

glycogen (gly' ko jen) [Gk. *glyk*: sweet] An energy storage polysaccharide found in animals and fungi; a branched-chain polymer of glucose, similar to starch.

- **Cellulose** is a very stable glucose polymer and is the principal structural component of plant cell walls.

cellulose (sell' you lowss) A straight-chain polymer of glucose molecules, used by plants as a structural supporting material.

▶ 3.4 Lipids Are Defined by Their Solubility Rather Than by Chemical Structure

- **Lipids** are hydrocarbons that are insoluble in water because of their many nonpolar covalent bonds. They play roles in energy storage, membrane structure, light harvesting, intercellular communication, and protection.

lipid (lip' id) [Gk. *lipos*: fat] Nonpolar, hydrophobic molecules that include fats, oils, waxes, steroids, and the phospholipids that make up biological membranes.

- **Fats** and **oils** are **triglycerides**. A triglyceride is composed of three **fatty acids** covalently bonded to a molecule of glycerol by **ester linkages**. **Review Figure 3.20**

fat (1) A triglyceride that is solid at room temperature. (Contrast with oil.) (2) Adipose tissue, one type of connective tissue. (See brown fat.)

oil A triglyceride that is liquid at room temperature. (Contrast with fat.)

triglyceride A simple lipid in which three fatty acids are combined with one molecule of glycerol.

fatty acid A molecule made up of a long nonpolar hydrocarbon chain and a polar carboxyl group. Found in many lipids.

ester linkage A condensation (water-releasing) reaction in which the carboxyl group of a fatty acid reacts with the hydroxyl group of an alcohol. Lipids, including most membrane lipids, are formed in this way. (Contrast with ether linkage.)

- A **saturated fatty acid** has a hydrocarbon chain with no double bonds. These molecules can pack together tightly. The hydrocarbon chain of an **unsaturated fatty acid** has one

or more double bonds that bend the chain, preventing close packing. **Review Figure 3.21**

unsaturated fatty acid A fatty acid whose hydrocarbon chain contains one or more double bonds. (Contrast with saturated fatty acid.)

- A **phospholipid** has a hydrophobic hydrocarbon “tail” and a hydrophilic phosphate “head”; that is, it is **amphipathic**. In water, the interactions of the tails and heads of phospholipids generate a **phospholipid bilayer**. The heads are directed outward, where they interact with the surrounding water. The tails are packed together in the interior of the bilayer, away from water. **Review Figure 3.22**

phospholipid A lipid containing a phosphate group; an important constituent of cellular membranes. (See lipid.)

amphipathic (am' fi path' ic) [Gk. *amphi*: both + *pathos*: emotion] Of a molecule, having both hydrophilic and hydrophobic regions.

phospholipid bilayer The basic structural unit of biological membranes; a sheet of phospholipids two molecules thick in which the phospholipids are lined up with their hydrophobic “tails” packed tightly together and their hydrophilic, phosphate-containing “heads” facing outward. Also called lipid bilayer.

- Other lipids include vitamins A, D, E, and K, steroids, and plant pigments such as carotenoids.

See Activity 3.4 to review macromolecule structures.

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify your understanding of this chapter. **LearningCurve** adapts to your responses, giving you the practice you need to master each key concept.

Dogs, like people, tend to have more health problems as they age. About one in every 100 dogs that reach age 12 loses the ability to synthesize insulin, a hormone in the body that regulates cell uptake of glucose from the blood. Veterinarians prescribe injections of porcine insulin for treatment. Porcine insulin is extracted from pigs' blood and has the same amino acid sequence as canine (dog) insulin. [Figure A](#) shows the structure of canine insulin, which is composed of two polypeptides, an A chain and a B chain, linked by disulfide bridges. [Figure B](#) shows how these chains fold to form secondary and tertiary structures. Labels A2, A3, A19, B23, and B24 indicate three amino acids on the A chain and two on the B chain thought to be directly involved in the binding of insulin to target proteins on body cell surfaces.

Source: Conlon, J. M. 2001. Evolution of the insulin molecule: Insights into structure-activity and phylogenetic relationships. *Peptides* 22: 1183–1193.

Note: A dash indicates the amino acid is the same as in the canine.

Since insulin is a protein found in all vertebrate animals, scientists have compared the structures of insulin from different vertebrate species. The table shows a comparison of a few amino acids in the A chain and B chain of insulins from a wide range of vertebrates.

Questions

1. What types of forces are involved in the binding of insulin to its target? What would be true about the positions of the amino acids A2, A3, A19, B23, and B24 that would allow them to be involved in binding?
2. What evidence shown in the table supports the hypothesis that amino acids A2, A3, A19, B23, and B24 are important in insulin's binding activity?
3. What conclusion can you draw about the finding that there are amino acid variations in some positions across vertebrate species? What could account for the finding that only certain amino acids are found at those positions and not at a wide range of amino acids?
1. Develop a hypothesis about the importance of cysteine residues in canine insulin. How could you test your hypothesis?

***connect the concepts** As discussed in [Key Concept 2.2](#), electronegativity is a measure of the attraction an atomic nucleus exerts on electrons in a covalent bond. When one interacting atom is much more electronegative than the other, a complete transfer of one or more electrons may take place.

4

Nucleic Acids and the Origin of Life

A camera on NASA's Mars *Curiosity* rover (inset) took this photo of the Martian surface in 2012. Note the mountains in the distance.

[4.3 The Large Molecules of Life Originated from Small Molecules](#)

investigatinglife

Looking for Life

On Earth you can find organisms and the chemical signatures of life everywhere—even deep under the sea, inside volcanoes, buried in ice, and floating in the air. Determining life's origin is difficult because (with few exceptions) the simple organisms that first existed left no fossils. On Mars, however, things might be different.

Mars has fascinated scientists (and science-fiction writers) since its discovery by astronomers more than 3,000 years ago. A cold planet, Mars has a geology that has changed little over several billion years, and so any evidence of life may be preserved. By the late nineteenth century, distinguished professors of astronomy firmly believed there was life on Mars, based on observations through telescopes that showed polar ice caps that changed with the seasons, darker areas thought to be liquid water, and even markings that resembled canals.

Better telescopes, chemical analyses based on light emission (spectroscopy), orbiting satellites, and landers controlled from Earth have laid to rest many of the initial ideas about life on Mars. But the challenge of finding present or past life on Mars remains. The search revolves around finding organisms, evidence of a current or past environment where life could exist, and chemical signatures of present or past life.

Unlike Earth, Mars now lacks a magnetic field to protect against cosmic radiation arriving from space. The surface of Mars is assaulted with very high levels of radiation, making it inhospitable to life. So any current life would have to be below the surface, where radiation is much lower.

Since life as we know it requires water, determining whether Mars now has or ever had water has been a central question. It is now established that water exists on the surface of Mars—at the poles, frozen, and in water vapor in its atmosphere. There is even evidence that trickles of water may exist on the surface, kept liquid in the bitter cold by a high salt concentration. The discovery of methane (CH_4) in the atmosphere of Mars has generated additional excitement and speculation. Might this methane be a by-product of an organic reaction? The search for evidence of the chemical elements (C, H, O, P, N, and S) of life introduced in [Chapter 2](#) continues.

Can we find evidence of life on Mars?

4.1 Nucleic Acid Structures Reflect Their Functions

Nucleic acids contain life's genetic code. From medicine to evolution, from agriculture to forensics, the properties of nucleic acids affect our lives every day. It is with nucleic acids that the concept of "information" entered the biological vocabulary. Nucleic acids are uniquely capable of coding for and transmitting biological information.

focus your learning

The structures of DNA and RNA enable their functions in storing and transferring genetic information.

Base pairing between nucleotides in DNA and RNA provides the structure needed for transfer of genetic information.

Base sequences of nucleotides in DNA provide the chemical diversity needed for storage of genetic information.

Nucleotides other than those found in DNA and RNA have diverse functions within the cell.

Nucleic acids are informational macromolecules

Nucleic acids are polymers specialized for the storage, transmission, and use of genetic information. There are two types of nucleic acids: **DNA (deoxyribonucleic acid)** and **RNA (ribonucleic acid)**. Although you have heard of it in countless pronouncements as a metaphor for the essence of something ("It's in her DNA"), DNA is first and foremost a macromolecule. Its structure encodes hereditary information and passes it from generation to generation. Through RNA intermediates, the information encoded in DNA specifies the amino acid sequences of proteins and controls the expression (that is, the synthesis) of other RNAs. In [Chapter 11](#) you will learn how, during cell division and reproduction, information is preserved from the DNA of the parental cell when both the cell and its DNA are duplicated to form two new daughter cells. [Chapter 13](#) will describe how information flows from DNA to RNA to the proteins that ultimately carry out many of life's functions. Here we focus on the chemistry of the nucleic acids, revealing how their structures reflect their functions.

nucleic acid (new klay' ik) A polymer made up of nucleotides, specialized for the storage, transmission, and expression of genetic information. DNA and RNA are nucleic acids.

DNA (deoxyribonucleic acid) The fundamental hereditary material of all living organisms. In eukaryotes, stored primarily in the cell nucleus. A nucleic acid using deoxyribose rather than ribose.

Nucleic acids are polymers composed of monomers called nucleotides. A **nucleotide** has three components: a nitrogen-containing **base**, a pentose sugar, and one to three phosphate groups ([Figure 4.1](#)). Molecules consisting of a pentose sugar and a nitrogenous base—but no phosphate group—are called **nucleosides**. The nucleotides that make up nucleic acids contain just one phosphate group—they are nucleoside *monophosphates*.

nucleotide The basic chemical unit in nucleic acids, consisting of a pentose sugar, a phosphate group, and a nitrogen-containing base.

base (1) A substance that can accept a hydrogen ion in solution. (Contrast with acid.) (2) In nucleic acids, the purine or pyrimidine that is attached to each sugar in the sugar–phosphate backbone.

nucleoside A nucleotide without the phosphate group; a nitrogenous base attached to a sugar.

The two groups of bases

Pyrimidines

Purines

Figure 4.1 Nucleotide Chemistry Nucleotide monomers, each consisting of a base, a sugar, and a phosphate group, are the building blocks of DNA and RNA polymers. The bases fall into two groups: the pyrimidines and the purines.

The bases of the nucleic acids take one of two chemical forms: a six-membered single-ring structure called a **pyrimidine**, or a fused double-ring structure called a **purine** (see [Figure 4.1](#)). In DNA, the pentose sugar is **deoxyribose**, which differs from the **ribose** found in RNA by the absence of one oxygen atom (see [Figure 3.16](#)).

pyrimidine (pe rim' a deen) One of the two types of nitrogenous bases in nucleic acids. Each of the pyrimidines—cytosine, thymine, and uracil—pairs with a specific purine.

purine (pure' een) One of the two types of nitrogenous bases in nucleic acids. Each of the purines—adenine and guanine—pairs with a specific pyrimidine.

deoxyribose A five-carbon sugar found in nucleotides and DNA.

ribose A five-carbon sugar in nucleotides and RNA.

A nucleic acid forms when nucleotide monomers are added to an existing chain one at a time. The pentose sugar in the last nucleotide of the existing chain and the phosphate on the new nucleotide undergo a condensation reaction (meaning H_2O is removed; see [Figure 3.4](#)), and the resulting bond is called a **phosphodiester linkage** ([Figure 4.2](#)). The phosphate on the incoming nucleotide is attached to the 5' carbon atom of its sugar, and the linkage occurs between it and the 3' carbon on the last sugar of the existing chain. Because each nucleotide is added to the 3' carbon of the last sugar, nucleic acids are said to *elongate in the 5'-to-3' direction*.

phosphodiester linkage The connection in a nucleic acid strand, formed by linking two nucleotides.

Figure 4.2 Linking Nucleotides Together Growth of a nucleic acid (RNA in this figure) from its monomers occurs in the 5' (phosphate) to 3' (hydroxyl) direction. Note that the added nucleotide is not initially a monophosphate but actually a triphosphate. The details of this process will be described in [Chapter 13](#).

As with carbohydrates (see [Key Concept 3.3](#)), nucleic acids can range in size. Oligonucleotides are relatively short, with about 20 nucleotide monomers, whereas polynucleotides can be much longer.

Oligonucleotides include RNA molecules that function as “primers” to begin the duplication of DNA; RNA molecules that regulate the expression of genes; and synthetic DNA molecules used for amplifying and analyzing other, longer nucleotide sequences.

Polynucleotides, more commonly referred to as nucleic acids, include DNA and some RNA. Polynucleotides can be very long, and indeed are the longest polymers in the living world. Some DNA molecules in humans contain hundreds of millions of nucleotides.

Base pairing occurs in both DNA and RNA

DNA and RNA differ somewhat in their sugar groups, bases, and strand structure ([Table 4.1](#)). Four bases are found in DNA: [adenine \(A\)](#), [cytosine \(C\)](#), [guanine \(G\)](#), and [thymine \(T\)](#). RNA is also made up of four different monomers, but its nucleotides include [uracil \(U\)](#) instead of thymine.

table 4.1 Distinguishing RNA from DNA

Nucleic acid	Sugar	Bases	Name of nucleoside	Strands
--------------	-------	-------	--------------------	---------

RNA	Ribose	Adenine	Adenosine	One
		Cytosine	Cytidine	
		Guanine	Guanosine	
		Uracil	Uridine	
DNA	Deoxyribose	Adenine	Deoxyadenosine	Two
		Cytosine	Deoxycytidine	
		Guanine	Deoxyguanosine	
		Thymine	Deoxythymidine	

adenine (A) (a' den een) A nitrogen-containing base found in nucleic acids, ATP, NAD, and other compounds.

cytosine (C) (site' oh seen) A nitrogen-containing base found in DNA and RNA.

guanine (G) (gwan' een) A nitrogen-containing base found in DNA, RNA, and GTP.

thymine (T) Nitrogen-containing base found in DNA.

uracil (U) A pyrimidine base found in nucleotides of RNA.

A key to understanding the structure and function of nucleic acids is the principle of **complementary base pairing**. In DNA, thymine and adenine pair (T-A), and cytosine and guanine pair (C-G). In RNA, the base pairs are A-U and C-G.

complementary base pairing The AT (or AU), TA (or UA), CG, and GC pairing of bases in double-stranded DNA, in transcription, and between tRNA and mRNA.

Base pairs are held together primarily by hydrogen bonds. As you can see, there are polar C=O and N—H covalent bonds in the bases; these can form hydrogen bonds between the δ^- on an oxygen or nitrogen of one base and the δ^+ on a hydrogen of another base.

Individual hydrogen bonds are relatively weak, but there are so many of them in a DNA or RNA molecule that collectively they provide a considerable force of attraction, which can bind together two polynucleotide strands, or a single strand that folds back onto itself. This attraction is not as strong as a covalent bond, however. This means that individual base pairs are relatively easy to break with a modest input of energy. As you will see, the breaking and making of hydrogen bonds in nucleic acids is vital to their role in living systems.

RNA

Even though RNA is generally single-stranded ([Figure 4.3A](#)), base pairing can occur between different regions of the molecule. Portions of the single-stranded RNA molecule can fold back and pair with one another ([Figure 4.3B](#)). Thus complementary hydrogen bonding between ribonucleotides plays an important role in determining the three-dimensional shapes of some RNA molecules. Complementary base pairing can also take place between ribonucleotides and deoxyribonucleotides. Adenine in an RNA strand can pair either with uracil (in another RNA strand) or with thymine (in a DNA strand). Similarly, an adenine in DNA can pair either with thymine (in the complementary DNA strand) or with uracil (in RNA).

(A) Single-stranded RNA

In RNA, the bases are attached to ribose. The bases in RNA are the purines adenine (A) and guanine (G) and the pyrimidines cytosine (C) and uracil (U).

(B) Complementary base pairing in regions of a single RNA molecule

Figure 4.3 RNA (A) RNA is usually a single strand. (B) When a single-stranded RNA folds back on itself, hydrogen bonds between complementary sequences can stabilize it into a three-dimensional shape with complex surface characteristics.

Q: What would happen if a folded RNA molecule were heated? Recall the effect of heat on hydrogen bonds.

DNA

Usually, ***DNA** is double-stranded; that is, it consists of two separate polynucleotide strands of the same length that are held together by hydrogen bonds between base pairs (**Focus: Key Figure 4.4A**). In contrast to RNA's diversity in three-dimensional structure, DNA is remarkably uniform. The A-T and G-C base pairs are about the same size (each is a purine paired with a pyrimidine), and the two polynucleotide strands form a "ladder" that twists into a **double helix** (**Focus: Key Figure 4.4B**). The sugar–phosphate groups form the sides of the ladder, and the bases with their hydrogen bonds form the "rungs" on the inside. DNA carries genetic information in its sequence of base pairs rather than in its three-dimensional structure. The key differences among DNA molecules are their different nucleotide base sequences.

focus: key figure

(A) A linear view of double-stranded DNA

(B) The DNA double helix

Figure 4.4 DNA (A) DNA usually consists of two strands running in opposite directions that are held together by hydrogen bonds between purines and pyrimidines on the two strands. (B) The two strands in DNA are coiled in a right-handed double helix.

Q: For replication or transcription, DNA must “unwind ” to expose bases. What bonds must be broken for this to occur?

double helix Refers to DNA and the (usually right-handed) coil configuration of two complementary, antiparallel strands.

DNA carries information and is expressed through RNA

DNA is an informational molecule. The information is encoded in the sequence of bases carried in its strands. For example, the information encoded in the sequence TCAGCA is different from the information in the sequence CCAGCA. DNA transmits information in two ways:

- DNA can be reproduced exactly. This process, called **DNA replication**, is done by polymerization using an existing strand as a base-pairing template.
- Certain DNA sequences can be copied into RNA, in a process called **transcription**. The nucleotide sequence in the RNA can then be used to specify a sequence of amino acids in a polypeptide chain, in the process called **translation**. The overall process of transcription and translation is called **gene expression**.

DNA replication The creation of a new strand of DNA in which DNA polymerase catalyzes the exact reproduction of an existing (template) strand of DNA.

transcription The synthesis of RNA using one strand of DNA as a template.

translation The synthesis of a protein (polypeptide). Takes place on ribosomes, using the information encoded in messenger RNA.

gene expression The transcription and translation into a protein of the information (nucleotide sequence) contained in a gene.

The details of these important processes will be described in later chapters, but it is important to realize two things at this point:

- *DNA replication and transcription depend on the base-pairing properties of nucleic acids.* Recall that the hydrogen-bonded base pairs are A-T and G-C in DNA and A-U and G-C in RNA. Consider, for example, this double-stranded DNA region:

5'-TCAGCA-3'

3'-AGTCGT-5'

Transcription of the lower strand will result in a single strand of RNA with the sequence 5'-UCAGCA-3'. Can you figure out the sequence that the top strand would produce?

- *DNA replication usually involves the entire DNA molecule.* Since DNA holds essential information, it must be replicated completely and accurately so that each new cell or new organism receives a complete set of DNA from its parent ([Figure 4.5A](#)). The complete set of DNA in a living organism is called its **genome**. However, not all of the information in the genome is needed at all times and in all tissues, and only small sections of the DNA are transcribed into RNA molecules. The sequences of DNA that are transcribed into RNA are called **genes** ([Figure 4.5B](#)).

Figure 4.5 DNA Replication and Transcription DNA is usually completely replicated **(A)** but only partially transcribed **(B)**. RNA transcripts are produced from genes that code for specific proteins. Transcription of different genes occurs at different times and, in multicellular organisms, in different cells of the body.

Q: What do you think determines whether a particular cell transcribes a sequence of DNA into RNA?

genome (jee' nome) The complete DNA sequence for a particular organism or individual.

gene [Gk. *genes*: to produce] A unit of heredity. Used here as the unit of genetic function which carries the information for a polypeptide or RNA.

In humans, the gene that encodes the major protein in hair (keratin) is expressed in skin cells that produce hair. The genetic information in the keratin-encoding gene is transcribed into RNA and then translated into a keratin polypeptide. In other tissues such as the muscles, the keratin gene is not transcribed, but other genes are—for example, the genes that encode proteins present in muscles but not in skin or hair. These genes are turned on and off by the control of gene expression, which we will describe in [Chapter 16](#).

The DNA base sequence reveals evolutionary relationships

DNA carries hereditary information from one generation to the next, gradually accumulating changes in its base sequences over long periods of time. A series of DNA molecules stretches back through the lineage of every organism to the beginning of biological evolution on Earth,

about 3.8 billion years ago. Therefore closely related living species have more similar base sequences than do species that are more distantly related. The same is true for closely related versus distantly related individuals within a species. The details of how scientists use this information will be covered in [Chapter 24](#).

Improvements in methods for DNA sequencing and analysis by computer programs have enabled scientists to determine the entire DNA base sequences—the genome—of many organisms, including humans, whose genome contains about 3 billion base pairs. These studies have confirmed many of the evolutionary relationships that had been inferred previously from more traditional comparisons of body structure, biochemistry, and physiology. For example, traditional comparisons had indicated that the closest living relative of humans (*Homo sapiens*) is the chimpanzee (genus *Pan*). In fact, the chimpanzee genome shares more than 98 percent of its DNA base sequence with the human genome. Increasingly, scientists turn to DNA analyses to elucidate evolutionary relationships when other comparisons are not possible or are not conclusive. For example, DNA studies revealed a close relationship between starlings and mockingbirds that was not expected on the basis of their anatomy or behavior.

Nucleotides have other important roles

Nucleotides are more than just the building blocks of nucleic acids. As we will describe in later chapters, there are several nucleotides (or modified nucleotides) with other functions:

ATP (adenosine triphosphate) acts as an agent of energy transfer in many biochemical reactions (see [Key Concept 8.2](#)).

GTP (guanosine triphosphate) serves as an energy source, especially in protein synthesis. It also plays a role in the transfer of information from the environment to cells (see [Key Concept 7.2](#)).

cAMP (cyclic adenosine monophosphate) is a special nucleotide with an additional bond between the sugar and the phosphate group. It is essential in many processes, including the actions of hormones and the transmission of information by the nervous system (see [Key Concept 7.3](#)).

Nucleotides play roles as carriers in the synthesis and breakdown of carbohydrates and lipids.

4.1 recap

The nucleic acids DNA and RNA are polymers made up of nucleotide monomers. The sequence of nucleotides in DNA carries the information that is used by RNA to specify primary protein structure. The genetic information in DNA is passed from generation to generation and can be used to understand evolutionary relationships.

learning outcomes

You should be able to:

- Explain how purines and pyrimidines differ.
- Explain how biological information is encoded in DNA.
- Identify cellular functions of nucleotides other than information processing.

1. What are the key differences between purines and pyrimidines and how does this relate to the structure of DNA?
2. How can DNA molecules be very diverse, even though they appear to be structurally

similar?

3. Single-stranded nucleic acids about 25 bases long are called aptamers. Because many sequences are possible, particular aptamers can be used to bind to specific targets, either as drugs to a protein target or for quantitating a small molecule in tissues or fluids. How can aptamers have such diversity and specificity for binding?

We have seen that the nucleic acids RNA and DNA carry the blueprint of life, and that the inheritance of these macromolecules reaches back to the beginning of evolutionary time. But when, where, and how did nucleic acids arise on Earth? How did the building blocks of life, such as amino acids and sugars, originally arise?

***connect the concepts** As explained in [Key Concept 13.2](#), the two strands of a DNA molecule fit together perfectly because they run in opposite directions—that is, they are antiparallel to one another. Equal distance between strands is maintained because a purine on one strand is always found opposite a pyrimidine on the other.

4.2 The Small Molecules of Life Originated on Primitive Earth

You learned in [Chapter 2](#) that living things are composed of the same elements as the inanimate universe (e.g., C, H, O, P, N, and S). But usually the arrangements of these atoms into molecules are unique in biological systems. You will not find biological molecules such as proteins in nonliving matter unless they came from a once-living organism.

focus your learning

Experimental evidence was used to refute the idea that life could arise from nonliving materials.

Water did not always exist on Earth, and its presence on Earth was necessary before life could arise.

Experimental evidence supports the theory that life evolved as the result of chemical and physical changes on early Earth.

Evidence discovered in meteorites and on Mars raises questions about whether life evolved on bodies other than Earth.

Living organisms do not repeatedly come from inanimate nature

We can't know for certain how life on Earth began. But one thing is sure: life (or at least life as we know it) is not constantly being restarted. That is, [spontaneous generation](#) of life from inanimate nature is not happening repeatedly before our eyes. Now and in the past, all life has come from life that existed before. But people, including scientists, did not always believe this.

spontaneous generation The idea that under ordinary circumstances, living organisms can form from non-living materials.

Many cultures and religions have suggested that life can arise repeatedly from nonliving matter. During the European Renaissance (from the fourteenth to seventeenth centuries, a period that witnessed the birth of modern science), most people thought that at least some forms of life arose repeatedly and directly from inanimate or decaying matter by spontaneous generation. People thought, for example, that mice arose from sweaty clothes placed in dim light; that frogs sprang directly from moist soil; and that rotting meat produced flies. One scientist who doubted these assumptions was the Italian physician and poet Francesco Redi. Redi hypothesized that flies arose not by some mysterious transformation of decaying meat, but from other flies that laid their eggs on the meat. In 1668, Redi performed a scientific experiment—a relatively new concept at the time—to test his hypothesis. He set out three jars containing chunks of meat:

- . One jar contained meat exposed to both air and flies.
- . A second jar was covered with a fine cloth so that the meat was exposed to air but not to flies.
- . The third jar was sealed with a lid so the meat was exposed to neither air nor flies.

As he had hypothesized, Redi found maggots, which then hatched into flies, only in the first jar. This finding demonstrated that maggots could occur only where flies were present before. The idea that a complex organism like a fly could appear spontaneously from a nonliving substance in the meat, or from “something in the air,” was laid to rest. Well, perhaps not quite to rest.

In the 1660s, the newly invented microscope revealed a vast biological world that had never been seen before. Virtually every environment on Earth was found to be teeming with tiny organisms. Some scientists believed these organisms arose spontaneously from their rich chemical environment, by the action of a “life force.” But experiments in the nineteenth century by the great French scientist Louis Pasteur showed that microorganisms can arise only from other microorganisms, and that an environment without life remains lifeless ([Figure 4.6](#)).

experiment

Figure 4.6 Disproving the Spontaneous Generation of Life

Source: Pasteur gave a talk on his research at the "Sorbonne Scientific Soirée" on April 7, 1864. This talk has been translated into English: rc.usf.edu/~levineat/pasteur.pdf.

Previous experiments disproving the spontaneous generation of larger organisms were called into question when microorganisms were discovered. Louis Pasteur's classic experiments disproved the spontaneous generation of microorganisms.

HYPOTHESIS ▶ Microorganisms come only from other microorganisms and cannot arise by spontaneous generation.

METHOD

RESULTS Microbial life grows only in the flasks exposed to microorganisms. There is no "spontaneous generation" of life in the sterile flask.

CONCLUSION ▶ Living organisms arise from preexisting living organisms.

Pasteur's and Redi's experiments showed that living organisms cannot arise from nonliving materials *under the conditions that exist on Earth now*. But their experiments did not prove that spontaneous generation never occurred. Eons ago, conditions on Earth and in the atmosphere above it were vastly different than they are today. Indeed, conditions similar to those found on primitive Earth may have existed, or may exist now, on other bodies in our solar system and elsewhere.

Life began in water

As we emphasized in [Chapter 2](#), water is an essential component of life as we know it. This is why there was great excitement when remotely controlled spacecraft sent from Earth detected water ice on Mars. Astronomers believe our solar system began forming about 4.6 billion years ago, when a star exploded and collapsed to form the sun and about 500 bodies called planetesimals. These planetesimals collided with one another to form the inner planets, including Earth and Mars. The first chemical signatures indicating the presence of life on Earth are about 4 billion years old. So it took 600 million years for the chemical conditions on Earth to become just right for life. Key among those conditions was the presence of water.

Ancient Earth probably had a lot of water high in its atmosphere. But the new planet was hot, and the water remained in vapor form and dissipated into space. As Earth cooled, it became possible for water to condense on the planet's surface—but where did that water come from? One current view is that comets (loose agglomerations of dust and ice that have orbited the sun since the planets formed) struck Earth and Mars repeatedly, bringing to those planets not only water but also other chemical components of life, such as nitrogen and carbon-containing molecules.

As the planets cooled and chemicals from their crusts dissolved in the water, simple chemical reactions would have taken place. Some of these reactions might have led to life, but impacts by large comets and rocky meteorites released enough energy to heat the developing oceans almost to boiling, thus destroying any early life that might have existed. On Earth, these large impacts eventually subsided, and around 3.8 billion years ago, life gained a foothold. There has been life on Earth ever since.

Several models have been proposed to explain the origin of life on Earth. The next sections will discuss two alternative theories: that life arose on Earth through chemical evolution, or that life came from outside Earth.

Prebiotic synthesis experiments model early Earth

One theory for the origin of life on Earth, [chemical evolution](#), holds that conditions on primitive Earth led to the formation of simple molecules such as monomers (see [Key Concept 3.1](#)), and that these molecules led to the formation of life forms. Scientists have sought to reconstruct those primitive conditions, both physically (by varying temperature) and chemically (by re-creating the mixes of elements that may have been present).

chemical evolution The theory that life originated through the chemical transformation of inanimate substances.

HOT CHEMISTRY

In oxygenated water, some trace metals such as molybdenum and rhenium are soluble, and their presence in sediments under oceans and lakes is directly proportional to the amount of oxygen gas (O₂) that was present in and above the water at the times the rocks were formed.

Measurements of dated sedimentary cores indicate that none of these rare metals was present prior to 2.5 billion years ago. This and other lines of evidence suggest that there was little O_2 in Earth's early atmosphere. Oxygen gas is thought to have accumulated about 2.5 billion years ago as the by-product of photosynthesis by single-celled life forms; today 21 percent of our atmosphere is O_2 .

In the 1950s Stanley Miller and Harold Urey at the University of Chicago set up an experimental "atmosphere" containing the gases they thought were present in Earth's early atmosphere: hydrogen gas, ammonia, methane gas, and water vapor. They passed an electrical spark through these gases to simulate lightning, a source of energy to drive chemical reactions. Then they cooled the system so the gases would condense and collect in a watery solution, or "ocean" ([Figure 4.7](#)). After a week of continuous operation, the system contained numerous organic molecules, including a variety of amino acids—the building blocks of proteins.

Animation 4.3 **Synthesis of Prebiotic Molecules** www.Life11e.com/a4.3

COLD CHEMISTRY

Stanley Miller also performed a long-term experiment in which the electrical spark was not used. In 1972 he filled test tubes with ammonia gas, water vapor, and cyanide (HCN), another molecule that is thought to have formed on primitive Earth. After checking that there were no contaminating substances or organisms that might confound the results, he sealed the tubes and cooled them to -78°C , the temperature of the ice that covers Europa, one of Jupiter's moons. Opening the tubes 27 years later, Miller found amino acids and nucleotide bases. Apparently, pockets of liquid water within the ice had allowed high concentrations of the starting materials to accumulate, thereby speeding up chemical reactions. The important conclusion is that the cold water within ice on ancient Earth, and other celestial bodies such as Mars, Europa, and Enceladus (one of Saturn's moons; satellite photos have revealed geysers of liquid water

coming from its interior), may have provided environments for the prebiotic synthesis of molecules required for the subsequent formation of simple living systems.

The results of these experiments were profoundly important in giving weight to speculations about the chemical origin of life on Earth and elsewhere in the universe. Decades of experimental work and critical evaluation followed Miller and Urey's original experiments. In science, an experiment and its results must be repeatable and be reinterpreted and refined as more knowledge accumulates. For example, ideas about Earth's original atmosphere have changed. There is abundant evidence indicating that major volcanic eruptions occurred 4 billion years ago; these would have released carbon dioxide (CO₂), nitrogen (N₂), hydrogen sulfide (H₂S), and sulfur dioxide (SO₂) into the atmosphere. Experiments using these gases in addition to the ones in the original Miller–Urey experiment have produced a more diverse list of organic products:

- All five bases that are present in DNA and RNA (i.e., A, T, C, G, and U)

- All of the 20 amino acids used in protein synthesis

- Many three- to six-carbon sugars

- Certain fatty acids

- Vitamin B₆ (pantothenic acid, a component of coenzyme A)

- Nicotinamide (part of NAD, which is involved in energy metabolism)

- Carboxylic acids such as succinic and lactic acids (also involved in energy metabolism)

Life may have come from outside Earth

In 1969 a remarkable event led to the discovery that a meteorite from space carried molecules that were characteristic of life on Earth. On September 28 of that year, fragments of a meteorite fell around the town of Murchison, Australia. Using gloves to avoid Earth-derived contamination, scientists immediately shaved off tiny pieces of the rock, put them in test tubes, and extracted them in water ([Figure 4.8](#)). They found several of the molecules that are unique to life, including purines, pyrimidines, sugars, and ten amino acids.

Figure 4.8 The Murchison Meteorite Pieces from a fragment of the meteorite that landed in Australia in 1969 were put into test tubes with water. Soluble molecules present in the rock—including amino acids, nucleotide bases, and sugars—dissolved in the water.

Were these molecules truly brought from space as part of the meteorite, or did they get there after the rock landed on Earth? There are a number of reasons to believe the molecules were not Earthly contaminants:

The scientists took great care to avoid contamination. They used gloves and sterile instruments, took pieces from below the rock's surface, and did their work very soon after the meteorite landed (they hoped before organisms from Earth could contaminate the samples).

Amino acids in most living organisms on Earth are L-amino acids; that is, the amino acids of living things are found in only one of the two possible optical isomeric forms (see [Figure 3.2](#)). The amino acids in the meteorite, however, were a mixture of L- and D-isomers, with a slight majority of the L form. Thus the amino acids in the meteorite were not likely to have come from a living organism on Earth.

In the story that opened [Chapter 2](#), we described how the ratio of isotopes in a living organism reflects the ratio of the same isotopes in the environment where the organism lives. The isotope ratios for carbon and hydrogen in the sugars from the meteorite were different from the ratios of those elements found on Earth.

More than 90 meteorites from Mars have been recovered on Earth. Many show signs of water—for example, in minerals such as carbonates that are precipitated from aqueous solution. Some also contain organic molecules that are the chemical signatures of life. While the presence of such molecules suggests that these rocks once harbored life, it does not prove that there were living organisms in the rocks when they landed on Earth. Many scientists find it hard to believe that an organism could survive thousands of years of traveling through space in a meteorite, followed by intense heat as the meteorite passed through Earth's atmosphere. But there is evidence that the heat at the centers of some meteorites may not have been extreme. If this were the case, then a long interplanetary trip by living organisms might have been possible.

Life does not have to reach Earth from space to prove it exists elsewhere. There is an ongoing search for life in celestial bodies. For example, as mentioned in the opening story of this chapter, both orbiting satellites and vehicles probing the landscape of Mars search for conditions suitable for present or past life on Mars. Perhaps the most dramatic attempt to discover life on Mars came in 1976, when NASA celebrated the 200th anniversary of the political independence of the United States by landing two stationary probes, or landers, called *Viking 1* and *Viking 2* on the planet. **Investigating Life: Can We Find Evidence of Life on Mars?** describes how scientists on Earth directed onboard instruments to evaluate soil on Mars for signs of life.

The logo for 'investigatinglife' features a red square with a yellow triangle pointing right, followed by the text 'investigatinglife' in white and yellow.

Life on Mars?

Can We Find Evidence of

experiment

Original Papers: Levin, G. V. and O. Straat. 1976. Viking labeled release biology experiment: Interim results. *Science* 194: 1322–1329.

Ponnamperuma, C., A. Shimoyama, M. Yamada, T. Hobo and R. Pal. 1977. Possible surface reactions on Mars: Implications for Viking biology results. *Science* 197: 455–457.

The *Viking* landers on Mars scooped up some of the soil and tested it for chemical interconversions consistent with life. Gilbert Levin and colleagues designed experiments to show remotely, at a distance of millions of miles, that there could be life on Mars at the present time.

HYPOTHESIS ▶ Martian soil can be tested by a probe on Mars to show chemical changes consistent with life.

METHOD

RESULTS

Radioactive gas detected (counts per minute) after 4 Martian days		
Control (no soil)	Martian sample 1	Martian sample 2
500	9,500	12,000

CONCLUSION ▶ Martian soil shows chemical changes consistent with life.

work with the data

While it's challenging to design experiments in the lab here on Earth, imagine the challenge of designing experiments done remotely on Mars! A team of biologists and chemists led by Levin and Straat sent instruments to Mars to test for the presence of life by measuring the emission of gases after nutrients were supplied to soils possibly containing Martian organisms. A scoop was used to obtain a 0.2 mL sample of soil which was then placed in a sealed container. The mixture was warmed to about 18°C (much higher than the surrounding Martian environment). Radioactive nutrients (formate, glycolate, glycine, alanine, and lactate) with their carbon atoms labeled in ^{14}C were added. At intervals after nutrient injection, a radioactive detector was employed to test for the release of ^{14}C radioactive gases.

QUESTIONS

- Table A shows data from two of the experiments. Plot the data as ^{14}C radioactive gas versus Martian days after nutrient addition. What can you conclude? Laboratory experiments prior to the two Viking departures showed that the total radioactivity that could be released if all of the nutrients were completely converted to gases was 257,000 counts per minute (cpm). Calculate the fraction of this that appeared in the Martian sample and comment on the result.
- Table A shows data from Martian soil that had been heated for 3 h at 160°C before nutrient addition. Plot these data on the same graph you made for Question 1. What types of molecules are destroyed by heat, and how does this occur? How do these data affect your conclusions from question 1?
- Back on Earth, Ponnamperuma and colleagues simulated Martian soil by using a major component of Martian soil called hematite (Fe_2O_3) and added the nutrients in the same way as had been done in the Mars experiment. Their results, including a preheated experiment, are shown in Table B. How do these results affect the conclusions you drew after considering Questions 1 and 2?

Table A

Time (days)	^{14}C Gases Detected (counts per minute)		
	Experiment 1	Experiment 2	Preheated soil
Initial	185	1,100	655
0.2	3,000	5,500	540
0.5	4,800	7,200	500
1.0	6,200	9,500	525
2.0	7,000	11,300	590
3.0	7,600	11,800	610
4.0	8,000	12,000	620

Table B

	^{14}C Gases Detected (counts per minute)	
	Hematite + ^{14}C nutrients	Hematite without nutrients
Experiment	10,140	150
Preheated 160°C	308	107

A similar **work with the data** exercise may be assigned in **LaunchPad**.

A distinctive aspect of living systems is their ability to use molecules from the environment to extract chemical energy for growth. During this process, waste products are released. You are familiar with this: you breathe in oxygen gas (O_2), take in nutrients in food, and breathe out carbon dioxide (CO_2). Other organisms do not use O_2 but take in other molecules. In the Mars experiments, scientists directed the Viking landers to scoop up some Martian soil and then exposed it to seven organic molecules as nutrients, all of which can be formed in Miller–Urey experiments (e.g., amino acids; see [Figure 4.7](#)). The seven molecules were labeled with a radioisotope of carbon (^{14}C). After a period of exposure, a detector was used to measure any radioactive gases (possibly CO_2) produced.

The results of some of the experiments were astonishing: radioactive gas was detected in some experiments, and some scientists concluded that there might be life on Mars. The fact that there was little radioactive gas produced when the soil was preheated to 160°C to kill living

organisms gave credence to this conclusion. Later, simulations in the lab on Earth showed that radioactive gas could be formed in this experiment with certain kinds of soils, without organisms. So there is an alternative, nonbiological explanation for the Mars data. Nevertheless, some biologists still adhere to the biological explanation for the Mars data, and the quest for life on Mars continues.

4.2 recap

Life does not arise repeatedly through spontaneous generation, but comes from preexisting life. Water is an essential ingredient for the emergence of life. Chemical synthesis experiments provide support for the idea that life's simple molecules formed in the prebiotic environment on Earth. Meteorites that have landed on Earth provide some evidence for an extraterrestrial origin of life, as do experiments with landers on Mars showing possible chemical interconversions that may reflect life.

learning outcomes

You should be able to:

- Explain how Redi's and Pasteur's experiments disproved spontaneous generation.
- Describe conditions on early Earth and theories about how these conditions affected the origin of life on Earth.
- Justify the conditions used by Miller and Urey in their experiments.

1. What conditions existing on Earth today might preclude the origin of life from the prebiotic molecules Miller and Urey used?
2. The interpretation of Pasteur's experiment (see [Figure 4.6](#)) depended on the inactivation of microorganisms by heat. We now know of microorganisms that can survive extremely high temperatures (see [Chapter 26](#)). Does this change the interpretation of Pasteur's experiment? What experiments would you do to inactivate such microbes?
3. The Miller-Urey experiment (see [Figure 4.7](#)) showed that it was possible for amino acids to be formed from gases that were hypothesized to have been in Earth's early atmosphere. These amino acids were dissolved in water. Knowing what you do about the polymerization of amino acids into proteins (see [Figure 3.6](#)), how would you set up an experiment to show that proteins can form under the conditions of early Earth?

Chemistry experiments modeling the conditions of ancient Earth provide clues about the origins of the monomers (such as amino acids) that make up the polymers (such as proteins) that characterize life. How did these polymers develop?

4.3 The Large Molecules of Life Originated from Small Molecules

The Miller–Urey experiment and others that followed provide a plausible scenario for the formation of the building blocks of life under conditions that prevailed on primitive Earth. The next step in forming and supporting a general theory on the origin of life would be an explanation for how polymers formed from these monomers.

focus your learning

Evidence from simulation experiments supports the theory that biological polymers formed from chemical reactions taking place in early Earth conditions.

Scientists hypothesize that the presence of catalysts would have been necessary during the evolution of biological polymers.

Complex molecules could be formed from simpler ones on primitive Earth

Scientists have used a number of model systems to try to simulate conditions under which the first biological polymers might have been made. Each of these systems is based on several observations and speculations:

Solid mineral surfaces, such as powderlike clays, have large surface areas. Scientists speculate that the silicates in clay may have catalyzed (sped up) the condensation reactions that resulted in organic polymers.

Hydrothermal vents deep in the ocean, where hot water emerges from beneath Earth's crust, lack oxygen gas and contain metals such as iron and nickel. In laboratory experiments, these metals have been shown to catalyze the polymerization of amino acids in the absence of oxygen.

In hot pools at the edges of oceans, evaporation may have concentrated monomers to the point where polymerization was favored (the “primordial soup” hypothesis).

In whatever ways the earliest stages of chemical evolution occurred, they resulted in the emergence of monomers and polymers that have probably remained unchanged in their general structures and functions for several billion years.

RNA may have been the first biological catalyst

Many chemical changes occur in living organisms: an example is DNA replication, which we described earlier in this chapter as the process by which a molecule of DNA is duplicated (see [Figure 4.5](#)). Many other chemical changes occur in living systems, often involving the hydrolysis or synthesis of macromolecules or conversions among small molecules. As you will see in [Chapter 8](#), these chemical changes can occur spontaneously in aqueous solutions like those that exist in biological systems, but most would occur extremely slowly. Catalysts—molecules that speed up biochemical conversions—solve this problem. So a key to the origin of life is the appearance of catalysts.

Today, the main catalysts in organisms are proteins called enzymes. The many shapes of proteins allow them to bind to diverse substances in solution and speed up chemical reactions. But we know that proteins are made based on information in nucleic acids. So we have a

chicken-or-egg problem: If proteins are needed for life, nucleic acids must have appeared first, so that the proteins could be made. But if nucleic acids appeared before proteins, proteins could not have been the first catalysts. Could nucleic acids be catalysts, in addition to their role as blueprints for protein synthesis? The answer is yes.

Like a protein, the three-dimensional structure of a folded RNA molecule presents a unique surface to the external environment (see [Figure 4.3](#)). The surfaces of RNA molecules can be every bit as specific as those of proteins. The three-dimensional shapes and other chemical properties of certain RNA molecules allow them to function as catalysts. Catalytic RNAs, called **ribozymes**, can speed up reactions involving their own nucleotides as well as other cellular substances. Although in retrospect it is not too surprising, the discovery of catalytic RNAs was a surprise to a community of biologists who were convinced that all biological catalysts were proteins (enzymes). It took almost a decade for the work of the scientists involved, Thomas Cech and Sidney Altman, to be fully accepted by other scientists, but when it was, the two were awarded the Nobel Prize.

ribozyme An RNA molecule with catalytic activity.
--

Given that RNA can be both informational (in its nucleotide sequence) and catalytic (because of its ability to form unique three-dimensional shapes), it has been hypothesized that early life consisted of an “RNA world”—a world before DNA. It is thought that when RNA was first made, it could have acted as a catalyst for its own replication as well as for the synthesis of proteins. DNA could eventually have evolved from RNA ([Figure 4.9](#)). Several lines of evidence support this scenario:

Figure 4.9 The “RNA World” Hypothesis This view postulates that in a world before DNA, RNA alone was both the blueprint for protein synthesis and a catalyst for its own replication. Eventually, the information storage molecules of DNA could have evolved from RNA.

In living organisms today, the formation of peptide linkages (see [Figure 3.6](#)) is catalyzed by ribozymes.

In certain viruses called retroviruses, there is an enzyme called reverse transcriptase that catalyzes the synthesis of DNA from RNA.

When a short, naturally occurring RNA molecule is added to a mixture of nucleotides, RNA polymers are formed at a rate 7 million times greater than the formation of polymers without the

added RNA. This indicates that the added RNA is a catalyst, not just a template.

An artificial ribozyme has been developed that can catalyze the assembly of short RNAs into a longer molecule that is an exact copy of itself. This may be how nucleic acid replication evolved.

4.3 recap

The formation of the large polymers that are characteristic of life may have occurred on the surfaces of clay particles, near hydrothermal vents, or in hot pools at the edges of oceans. RNA may have been the first genetic material and catalyst.

learning outcomes

You should be able to:

- Justify the need for catalysts in the origin of life.
 - Describe the proposed role for RNA in the formation of long-chain polymers.
 - Provide evidence supporting RNA as a catalyst in prebiotic chemical reactions that gave rise to other biological polymers.
-
1. Why was the ability to both encode information and catalyze reactions important for the origin of life?
 2. Why was the discovery of ribozymes important for the development of the “RNA world” hypothesis?
 3. In living organisms, the catalyst for the formation of the peptide bond is an RNA that does not have an informational role. How does this relate to the “RNA world” hypothesis?

The discovery of mechanisms for the formation of small and large molecules is essential to answering questions about the origin of life on Earth. But we also need to understand how organized living systems formed. Such systems display the characteristic properties of life, including reproduction, energy processing, and responsiveness to the environment. These are properties of cells, whose origin we will explore in the next section.

4.4 Cells Originated from Their Molecular Building Blocks

As you have seen from many of the theories on the origin of life, the evolution of biochemistry occurred under localized conditions. That is, the chemical reactions of life could not occur in a dilute aqueous environment with the molecular participants far apart. There had to be a compartment of some sort that brought together and concentrated the compounds involved in these events. Biologists have proposed that initially this compartment may have simply been a tiny droplet of water on the surface of a rock. But another major event in the origin of life was necessary: the evolution of the cell membrane.

focus your learning

Membrane development was critical for the evolution of the cell as the smallest unit of life. Scientists have discovered fossils of structures that may have been early cells.

Life as we know it is separated from the environment within structurally defined units called **cells**. The internal contents of a cell are separated from the nonbiological environment by a special barrier—a **membrane**. The membrane is not just a barrier; it regulates what goes into and out of the cell, as we will describe in [Chapter 6](#). This role of the surface membrane is very important because it permits the interior of the cell to maintain a chemical composition that is different from that of its external environment.

membrane A phospholipid bilayer forming a barrier that separates the internal contents of a cell from the nonbiological environment, or enclosing the organelles within a cell. The membrane regulates the molecular substances entering or leaving a cell or organelle.

How did the first cells with membranes come into existence?

Jack Szostak and his colleagues at Harvard University built a laboratory model that gives insights into the origin of cells. To do this, they first put fatty acids (which can be made in prebiotic experiments) into water. Recall from [Chapter 3](#) that fatty acids are amphipathic: they have a hydrophilic polar head and a long, nonpolar tail that is hydrophobic (see [Figure 3.22](#)). When placed in water, fatty acids will arrange themselves in a round “huddle” much like a football team: the hydrophilic heads point outward to interact with the aqueous environment, and the fatty acid tails point inward, away from the water molecules.

What if some water becomes trapped in the interior of this “huddle”? Now the layer of hydrophobic fatty acid tails is in water, which is an unstable situation. To stabilize this structure, a second layer of fatty acids forms. This **lipid bilayer** has the polar heads of the fatty acids facing both outward and inward, because they are attracted to the polar water molecules present on each side of the double layer. The nonpolar tails form the interior of the bilayer ([Figure 4.10](#)). These prebiotic, water-filled structures, defined by a lipid bilayer membrane, very much resemble living cells. Scientists refer to these compartments as **protocells**. Examining their properties revealed that:

lipid bilayer See phospholipid bilayer.

protocells A self-organized sphere of lipids proposed as a stepping-stone to the origin of life.

(A) Hypothetical formation of a protocell

(B) Model of a protocell

Figure 4.10 Protocells (A) In a series of experiments, Jack Szostak and his colleagues mixed fatty acid molecules in water. The molecules formed spherical structures called protocells, with water surrounded by bilayers of fatty acids. (B) A model of a protocell. A portion of the “membrane” has been cut away to reveal the inside of the protocell and the membrane’s bilayer structure. Nutrients and nucleotides pass through the “membrane” and enter the protocell, where they copy an already present RNA template. The new copies of RNA remain in the protocell.

Large molecules such as DNA and RNA could not pass through the bilayer to enter the protocells, but small molecules such as sugars and individual nucleotides could.

Nucleic acids inside the protocells could replicate using the nucleotides from outside. When the investigators placed a short nucleic acid strand capable of self-replication inside protocells and added nucleotides to the watery environment outside, the nucleotides crossed the barrier, entered the protocells, and became incorporated into new polynucleotide chains. This replication, which can occur without protein catalysis, may have been the first step toward cell reproduction.

Were these protocells truly cells, and was the lipid bilayer produced in these experiments a true cell membrane? Certainly not. The protocells could not fully reproduce, nor could they carry out all the metabolic reactions that take place in modern cells. The simple lipid bilayer had few of the sophisticated functions of modern cell membranes. Nevertheless, the *protocell may be a reasonable facsimile of a cell as it evolved billions of years ago:

It can act as an organized system of parts, with substances interacting and reacting, in some cases catalytically.

It includes an interior that is distinct from the exterior environment.

It is capable of limited replication.

These are all fundamental characteristics of living cells.

Some ancient cells left a fossil imprint

In the 1990s scientists made a rare find: a formation of ancient rocks in Australia that had remained relatively unchanged since the rocks first formed 3.5 billion years ago. In one of these rock samples, geologist J. William Schopf of the University of California, Los Angeles, saw chains and clumps of what looked tantalizingly like contemporary cyanobacteria, or “blue-green” bacteria ([Figure 4.11](#)). Cyanobacteria are believed to have been among the first organisms because they can perform photosynthesis, converting CO₂ and water into carbohydrates. Schopf needed to prove that the chains were once alive, not just the results of simple chemical reactions. He and his colleagues looked for chemical evidence of photosynthesis in the rock samples.

Figure 4.11 The Earliest Cells? This fossil from Western Australia is 3.5 billion years old. Its form is similar to that of modern filamentous cyanobacteria (inset).

The use of carbon dioxide in photosynthesis is a hallmark of life and leaves a unique chemical signature—a specific ratio of carbon isotopes (^{13}C : ^{12}C) in the resulting carbohydrates. Schopf showed that the Australian material had this isotope signature. Furthermore, microscopic examination of the chains revealed *internal* substructures that are characteristic of living systems and were not likely to be the result of simple chemical reactions. Schopf's evidence suggests that the Australian sample is indeed the remains of a truly ancient living organism.

In 2011 a different team of scientists, working about 32 km from Schopf's discovery, found similar-looking microfossil structures in sandstone rocks that were about 3.4 billion years old. In this case, a chemical analysis of the rocks indicated that these cells used sulfur instead of oxygen in the series of cellular reactions that release chemical energy.

Taking geological, chemical, and biological evidence into account, it is plausible that it took about 500 million to a billion years from the formation of Earth until the appearance of the first cells ([Figure 4.12](#)). Life has been cellular ever since. In the next chapter we will begin our study of cell structure and function.

Figure 4.12 The Origin of Life This highly simplified time line gives a sense of the major events that culminated in the origin of life more than 3.5 billion years ago.

4.4 recap

The chemical reactions that preceded living organisms probably occurred in specialized compartments, such as water droplets on the surfaces of minerals. Life as we know it did not begin until the emergence of cells. Protocells made in the laboratory have some of the properties of modern cells. Cell-like structures fossilized in ancient rocks date early cells to about 3.5 billion years ago.

learning outcomes

You should be able to:

- Justify the reasoning behind the hypothesis that a membrane was critical in the evolution of life on Earth.
- Describe the evidence suggesting that microfossils may be the remains of early cells.

1. Why is the cell membrane important to the evolution of living organisms?
2. If you wanted to find evidence for the existence of cells more than 3 billion years ago, what would you look for?

QA Can we find evidence of life on Mars?

In 2014, NASA declared that finding evidence for current or past life on Mars is a primary goal. At this writing, the *Curiosity* rover is still there, doing experiments and analyses. Later rovers are planned for early in the coming decade. In addition, the European Space Agency, collaborating with Russia, is planning to launch several “ExoMars” rovers in the middle of the decade, which will drill 2 m into the surface of Mars to get cores to analyze them for chemical traces of life below the surface. Most exciting, although uncertain, is a Mars Sample Return Mission, in which soil samples will be brought back to Earth for careful experimentation and analysis in laboratories, just as samples from the moon were brought back more than 40 years ago. If you had a Martian soil sample here on Earth, what analyses and experiments would you perform?

Future directions

A daring space mission is in the final planning stages that may provide key information on the origin of life on Earth. There are more than 600,000 known asteroids, most of them rocks from the early solar system orbiting the sun between Mars and Jupiter. But a few thousand have been kicked out of the typical location and are relatively near Earth, some getting closer than our moon. One, called Bennu, was discovered in 1999 and has been well studied. It is just the right size and composition to contain organic molecules. In 2018, a probe called OSIRIS-REx will arrive at the asteroid, spend about a year near it, and collect a sample of material and then return it to Earth in 2023 for analysis. This sample of the early solar system will provide scientists with a window onto not just what the asteroid is made of, but perhaps the earliest molecules that could have led to life.

► 4.1 Nucleic Acid Structures Reflect Their Function

- The unique functions of the **nucleic acids**—DNA and RNA—are information storage and transfer. DNA is the hereditary material that passes genetic information from one generation to the next, and RNA uses that information to specify the structures of proteins.

nucleic acid (new klay' ik) A polymer made up of nucleotides, specialized for the storage, transmission, and expression of genetic information. DNA and RNA are nucleic acids.

- Nucleic acids are polymers of nucleotides. A **nucleotide** consists of a phosphate group, a pentose sugar (**ribose** in RNA and **deoxy-ribose** in DNA), and a nitrogen-containing **base**. !!Review [Figure 4.1](#), [Animation 4.1](#), [Activity 4.1](#)

nucleotide The basic chemical unit in nucleic acids, consisting of a pentose sugar, a phosphate group, and a nitrogen-containing base.

ribose A five-carbon sugar in nucleotides and RNA.

base (1) A substance that can accept a hydrogen ion in solution. (Contrast with acid.) (2) In nucleic acids, the purine or pyrimidine that is attached to each sugar in the sugar–phosphate backbone.

- In DNA, the nucleotide bases are **adenine** (A), **guanine** (G), **cytosine** (C), and **thymine** (T). **Uracil** (U) replaces thymine in RNA. C, T, and U have single-ring structures and are **pyrimidines**. A and G have double-ring structures and are **purines**.

adenine (A) (a' den een) A nitrogen-containing base found in nucleic acids, ATP, NAD, and other compounds.

guanine (G) (gwan' een) A nitrogen-containing base found in DNA, RNA, and GTP.

cytosine (C) (site' oh seen) A nitrogen-containing base found in DNA and RNA.

thymine (T) Nitrogen-containing base found in DNA.

uracil (U) A pyrimidine base found in nucleotides of RNA.

pyrimidine (pe rim' a deen) One of the two types of nitrogenous bases in nucleic acids. Each of the pyrimidines—cytosine, thymine, and uracil—pairs with a specific purine.

purine (pure' een) One of the two types of nitrogenous bases in nucleic acids. Each of the purines—adenine and guanine—pairs with a specific pyrimidine.

- The nucleotides in DNA and RNA are joined by **phosphodiester linkages** involving the sugar of one nucleotide and the phosphate of the next, forming a nucleic acid polymer. !!Review [Figure 4.2](#), [Activity 4.2](#)

phosphodiester linkage The connection in a nucleic acid strand, formed by linking two

nucleotides.

- **Complementary base pairing** due to hydrogen bonds between A and T, A and U, and G and C occurs in nucleic acids. In RNA, the hydrogen bonds result in a folded molecule. In DNA, the hydrogen bonds connect two strands into a double helix. !!**Review Figure 4.3, Focus: Key Figure 4.4**

complementary base pairing The AT (or AU), TA (or UA), CG, and GC pairing of bases in double-stranded DNA, in transcription, and between tRNA and mRNA.

- The information content of DNA and RNA resides in their base sequences.
- The information in DNA is expressed as RNA in **transcription**. RNA can then specify the amino acid sequence of a protein in **translation**. **Review Figure 4.5**

transcription The synthesis of RNA using one strand of DNA as a template.

translation The synthesis of a protein (polypeptide). Takes place on ribosomes, using the information encoded in messenger RNA.

▶ 4.2 The Small Molecules of Life Originated on Primitive Earth

- The historical belief that life can originate repeatedly by **spontaneous generation** was disproven experimentally. !!**Review Figure 4.6, Animation 4.2**

spontaneous generation The idea that under ordinary circumstances, living organisms can form from non-living materials.

- A prerequisite for life is the presence of water.
- One hypothesis for the origin of life on Earth is **chemical evolution**: the idea that organic molecules were formed on Earth before life began.

chemical evolution The theory that life originated through the chemical transformation of inanimate substances.

- Chemical experiments modeling the prebiotic conditions on Earth support the idea of chemical evolution. !!**Review Figure 4.7, Animation 4.3**
- Some meteorites that have landed on Earth contain organic molecules, suggesting that life might have originated extraterrestrially.
- Experiments with lands on Mars yielded some data consistent with the existence of life on that planet. **Review Investigating Life: Can We Find Evidence of Life on Mars?**

▶ 4.3 The Large Molecules of Life Originated from Small Molecules

- Chemical evolution may have led to the polymerization of small molecules into polymers. This may have occurred on the surfaces of clay particles, in hydrothermal vents, or in hot pools at the edges of oceans.
- A catalyst speeds up a chemical reaction. Today most catalysts are proteins, but some RNA molecules can function as both catalysts and information molecules. A catalytic RNA is called a **ribozyme**.

ribozyme An RNA molecule with catalytic activity.

- The existence of ribozymes supports the idea of an “rRNA world”— a world before DNA. On early Earth, RNA may have acted as a catalyst for its own replication as well as for the synthesis of proteins. DNA could eventually have evolved from RNA. **Review Figure 4.9**
- In support of the “rRNA world” hypothesis, an artificial self-replicating ribozyme was developed in the laboratory. **Review Figure 4.10**

▶ 4.4 Cells Originated from Their Molecular Building Blocks

- A key to the emergence of living cells was the prebiotic generation of compartments enclosed by **membranes**. Such enclosed compartments permitted the generation and maintenance of internal chemical conditions that were different from those in the exterior environment.

membrane A phospholipid bilayer forming a barrier that separates the internal contents of a cell from the nonbiological environment, or enclosing the organelles within a cell. The membrane regulates the molecular substances entering or leaving a cell or organelle.

- In the laboratory, fatty acids assemble into **protocells** that have some of the characteristics of cells. **Review Figure 4.11**

protocells A self-organized sphere of lipids proposed as a stepping-stone to the origin of life.

- Ancient rocks (3.5 billion years old) have been found with imprints that are probably fossils of early cells.

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify your understanding of this chapter. **LearningCurve** adapts to your responses, giving you the practice you need to master each key concept.

► Apply What You've Learned

Review

- 1 The structures of the polynucleotides DNA and RNA enable their functions in storing and transferring genetic information.
- 2 Base pairing between nucleotides in the polynucleotides DNA and RNA provides the structure needed for transfer of genetic information.
- 3 Base sequences of nucleotides in DNA provide the chemical diversity needed for storage of genetic information.
- 1 Nucleotides other than those found in DNA and RNA have diverse functions within the cell.

Original Paper: Chargaff, E. 1950. Chemical specificity of nucleic acids and mechanisms for their enzymatic degradation. *Experientia*. 6: 201–240.

Nucleic acids show structural similarity across organisms, whether you're looking at DNA from a bacterium, a wheat plant, or a human. If you run chemical analyses on DNA extracted from several organisms, you always find a one-to-one molar ratio of phosphate groups to deoxyribose groups. This one-to-one ratio results from the repeating backbone structure of DNA, which is constructed from many nucleotide monomers polymerized together. All organisms share this structural similarity.

You know, however, that DNA from different organisms is not identical. After all, DNA carries biological information specific to each organism. What can you learn about DNA if you analyze base composition across several species? What can you learn about RNA? The tables below provide data for analyzing these questions.

Questions

- 1 Calculate the purine-to-pyrimidine ratio for each DNA data set. What pattern do you observe? What does this pattern indicate about DNA structure?
- 2 Calculate the purine-to-pyrimidine ratio for each RNA data set. What pattern do you observe? What does this pattern indicate about RNA structure?
- 3 What is the significance of any difference in patterns you found for DNA and RNA as you answered Questions 1 and 2?
- 4 Calculate the combined AT content and combined GC content in the DNA of each organism listed in the table. How does DNA from different organisms compare with respect to this calculation?
- 5 Identify two organisms having similar AT content and GC content in their DNA from your answer to Question 4. Explain how these organisms can share this similarity yet have completely different genetic makeups.

Organism and tissue	DNA base composition (%)			
	Adenine	Guanine	Cytosine	Thymine
Herring sperm	27.8	22.2	22.6	27.5
Rat bone marrow	28.6	21.4	21.5	28.4
Human sperm	30.7	19.3	18.8	31.2
Escherichia coli	26.0	24.9	25.2	23.9
Yeast	31.3	18.7	17.1	32.9

RNA base composition (%)			
--------------------------	--	--	--

Organism and tissue	Adenine	Guanine	Cytosine	Uracil
Rat liver	19.2	28.5	27.5	24.8
Carp muscle	16.4	34.4	31.1	18.1
Yeast	25.1	30.2	20.1	24.6
Rabbit liver	19.7	26.8	25.8	27.6
Cat brain	21.6	31.8	26.0	20.6

Natural Sunscreen

Sunlight plays a key role in life, providing the energy that is transformed into stored chemical energy in green plants through the process of photosynthesis. When we eat food, the energy stored in its chemical bonds ultimately came from the sun. But sunlight has a nasty side effect: part of it, the highly energetic ultraviolet light, damages the genetic material, DNA. Even without knowing this chemistry, some people take measures to minimize exposure to excess sunlight, either by staying in the shade or using chemical sunscreens. But there is also a biological mechanism that has evolved to reduce the sun's damage to organisms. In most animals, dark brown or black chemical pigments called melanins are made inside cells, the basic units of life. Melanins absorb ultraviolet light, thereby protecting DNA.

In humans, melanin is made in certain skin cells called melanocytes. Humans first evolved in Africa, and the intense sunlight near the equator acted as an evolutionary selective agent for the development of large numbers of melanocytes. As some of these dark-skinned people migrated to more northern regions where the sun is not as intense, the selection pressure for melanocytes was reduced, and over millennia, genetic changes leading to fewer melanocytes persisted in offspring, resulting in lighter skin. Exposure to intense sunlight in these people results in the production of more melanin, the familiar tanning response.

Melanocytes are specialized cells. You find them in the skin but not typically in internal organs. We will return to the process of how different cells have different functions in later chapters. But even inside the melanocyte, there is specialization. Melanin is made inside a special cell compartment called the melanosome. These compartments can be expelled from melanocytes and transferred to other skin cells, so they too become loaded with pigment. This occurs spontaneously in dark-skinned people, while in paler people it is stimulated by exposure to intense sunlight.

The observation that the chemistry of life takes place within cells, and in some cases within specialized compartments in them, is a key concept of biological science.

Are pigments compartmentalized in all types of cells?

5.1 Cells Are the Fundamental Units of Life

[Chapter 1](#) introduced some of the characteristics of life: chemical complexity, growth and reproduction, the ability to refashion substances from the environment, and the ability to move specific substances into and out of the organism. Cells have all of these characteristics. Just as atoms are the building blocks of chemistry, cells are the building blocks of life.

focus your learning

Cell theory states that the cell is the smallest unit of life, that cells make up all living organisms, and that cells come from existing cells.

Microscopy allows visual examination of cells.

Membranes provide a structural role in a cell and also allow the cell to maintain homeostasis and communicate with other cells.

What is the cell theory?

The [cell theory](#) is an important unifying principle of biology. There are three components of the cell theory:

cell theory States that cells are the basic structural and physiological units of all living organisms, and that all cells come from preexisting cells.

- . Cells are the fundamental units of life.
- . All living organisms are composed of cells.
- . All cells come from preexisting cells.
To the original cell theory, first stated in 1838, should be added:
- . Modern cells evolved from a common ancestor.

Cells contain water and other small and large molecules, which we examined in [Chapters 2–4](#). Each cell contains at least 10,000 different types of molecules, most of them present in many copies. Cells use these molecules to transform matter and energy, to respond to their environments, and to reproduce. The cell theory has three important implications:

- . Studying cell biology is in some sense the same as studying life. The principles that underlie the functions of the single cell of a bacterium are similar to those governing the approximately 60 trillion human cells of your body.
- . Life is continuous. All the cells in your body came from a single cell, a fertilized egg (zygote). That zygote came from the fusion of two cells, a sperm and an egg, from your parents. The cells of your parents' bodies were all derived from their parents, and so on back through generations and evolution to the initial cell.
- . The origin of life on Earth was marked by the origin of the first cells (see [Chapter 4](#)).

Even the largest creatures on Earth are composed of cells, but the cells themselves are usually too small for the naked eye to see. Why are cells so small?

Cell size is limited by the surface area-to-volume ratio

Most cells are tiny. In 1665 Robert Hooke estimated that in 1 square inch of cork, which he examined under his magnifying lens, there were 1,259,712,000 cells! The diameters of cells range from about 1 to 100 micrometers (μm). There are some exceptions: the eggs of birds are large single cells, and individual cells of several types of algae and bacteria are large enough to be viewed with the unaided eye (**Figure 5.1**).

Figure 5.1 The Scale of Life This logarithmic scale shows the relative sizes of molecules, cells, and multicellular organisms.

Activity 5.1 The Scale of Life www.Life11e.com/ac5.1

Small cell size is a practical necessity arising from the change in the **surface area-to-volume ratio** of any object as it increases in size. As an object increases in volume, its surface area also increases, but not at the same rate (**Figure 5.2**). This phenomenon has great biological significance. To appreciate this point, let's assume that the amount of chemical activity carried out by a cell is proportional to its volume. The surface area of the cell determines the amount of substances that can enter it from the outside environment, and the amount of waste products that can exit to the environment.

surface area-to-volume ratio For any cell, organism, or geometrical solid, the ratio of surface area to volume; this is an important factor in setting an upper limit on the size a cell or organism can attain.

Diameter	2 μm	20 μm	200 μm
Surface area $4 \pi r^2$	12.6 μm^2	1,260 μm^2	126,000 μm^2
Volume $\frac{4}{3} \pi r^3$	4.2 μm^3	4,200 μm^3	4,200,000 μm^3
Surface area- to-volume ratio	3.0:1	0.3:1	0.003:1

Figure 5.2 Why Cells Are Small As an object grows larger, its volume increases more rapidly than its surface area. Cells must maintain a large surface area-to-volume ratio in order to function. This explains why large organisms are composed of many small cells rather than a few huge ones.

As a living cell grows larger, its chemical activities, and thus its need for resources and its rate of waste production, increase faster than its surface area. (The surface area, being two-dimensional, increases in proportion to the square of the radius, whereas the volume, being three-dimensional, increases much more—in proportion to the cube of the radius.) In addition, substances must move from one site to another within the cell; the smaller the cell, the more easily this is accomplished. This explains why large organisms must consist of many small cells: cells must be small in volume in order to maintain a large enough [surface area-to-volume ratio](#) and an ideal internal volume. The large surface area represented by the many small cells of a multicellular organism enables it to carry out the many different functions required for survival.

surface area-to-volume ratio For any cell, organism, or geometrical solid, the ratio of surface area to volume; this is an important factor in setting an upper limit on the size a cell or organism can attain.

Microscopes reveal the features of cells

Most cells are too small to be seen with the unaided eye. Microscopes allow cells and details within them to be seen. The property that allows detail to be seen is called resolution. Formally defined, resolution is the minimum distance two objects can be apart and still be seen as two objects. Resolution for the human eye is about 0.2 mm (200 μm). Most cells are much smaller than 200 μm and thus are invisible to the human eye. Microscopes magnify and increase resolution so that cells and their internal structures can be seen clearly ([Figure 5.3](#)).

Figure 5.3 Looking at Cells The six images on this page show some techniques used in light microscopy. The three images on the following page were created using electron microscopes. All of these images are of a particular type of cultured cell known as HeLa cells.

Note that the images in most cases are flat, two-dimensional views. As you look at images of cells, keep in mind that they are three-dimensional structures.

 Activity 5.2 Know Your Techniques www.Life11e.com/ac5.2

In a *light microscope*, glass lenses and visible light are used to form an image. The resolution is about $0.2\ \mu\text{m}$, which is 1,000 times greater than that of the human eye. Light microscopy allows visualization of cell sizes and shapes and some internal cell structures. Internal structures are hard to see under visible light, so cells are often chemically treated and stained with various dyes to make certain structures stand out by increasing contrast.

In **bright-field microscopy**, light passes directly through these human cells. Unless natural pigments are present, there is little contrast and details are not distinguished.

30 μ m

In **phase-contrast microscopy**, contrast in the image is increased by emphasizing differences in refractive index (the capacity to bend light), thereby enhancing light and dark regions in the cell.

30 μ m

Differential interference-contrast microscopy uses two beams of polarized light. The combined images look as if the cell is casting a shadow on one side.

30 μ m

In **stained bright-field microscopy**, a stain enhances contrast and reveals details not otherwise visible. Stains differ greatly in their chemistry and their capacity to bind to cell materials, so many choices are available.

In **fluorescence microscopy**, a natural substance in the cell or a fluorescent dye that binds to a specific cell material is stimulated by a beam of light, and the longer-wavelength fluorescent light is observed coming directly from the dye.

Confocal microscopy uses fluorescent materials but adds a system of focusing both the stimulating and emitted light so that a single plane through the cell is seen. The result is a sharper two-dimensional image than with standard fluorescence microscopy.

Transmission electron microscope

In an *electron microscope*, electromagnets are used to focus an electron beam, much as a light microscope uses glass lenses to focus a beam of light. Since we cannot see electrons, the electron microscope directs them through a vacuum at a fluorescent screen or digital camera to create a visible image. The resolution of electron microscopes is about 2 nm, which is about 100,000 times greater than that of the human eye. This resolution permits the details of many subcellular structures to be distinguished.

In **transmission electron microscopy** (TEM), a beam of electrons is focused on the object by magnets. Objects appear darker if they absorb the electrons. If the electrons pass through they are detected on a fluorescent screen.

Scanning electron microscopy (SEM) directs electrons to the surface of the sample, where they cause other electrons to be emitted. These electrons are viewed on a screen. The three-dimensional surface of the sample can be visualized.

In **freeze-fracture microscopy**, cells are frozen and then a knife is used to crack them open. The crack often passes through the interior of cell and internal membranes. The “bumps” that appear are usually large proteins or aggregates embedded in the interior of the membrane.

There are two basic types of microscopes—light microscopes and electron microscopes—that use different forms of radiation (see [Figure 5.3](#)). While the resolution is better in electron microscopy, only dead cells are visualized because they must be prepared in a vacuum. Light microscopes, by contrast, can be used to visualize living cells (for example, by phase-contrast microscopy; see [Figure 5.3](#)).

Before we look at cell structure, it is useful to consider the many uses of microscopy. Here is an example: an entire branch of medicine, pathology, makes use of many different methods of microscopy to aid in the analysis of cells and the diagnosis of diseases. For instance, a surgeon might remove from a body some tissue suspected of being cancerous. The pathologist might:

- examine the tissue quickly by phase-contrast microscopy to determine the size, shape, and spread of the cells;

- stain the tissue with a general dye and examine it by bright-field microscopy to bring out features such as the shapes of the nuclei, or cell division characteristics;

examine the tissue under the transmission electron microscope to observe internal structures such as the mitochondria or the chromatin (these are described in [Key Concept 5.3](#));

stain the tissue with a specific dye and examine it by microscopy for the presence of proteins that are diagnostic of particular cancers. The results can influence the choice of therapy.

The cell membrane forms an outer boundary of every cell

While light microscopy shows many types of cells and even some structure inside them, the [cell membrane](#) is best observed with an electron microscope. This very thin structure forms the outer boundary of the cytoplasm of every cell, and it has similar thickness and molecular structure in all cells. You will learn about membranes in more detail in [Chapter 6](#). For now, keep in mind that (with the exception of some species of archaea discussed in [Chapter 26](#)) the cell membrane consists of a phospholipid bilayer (see [Key Concept 3.4](#)), and that a variety of proteins are embedded within the bilayer.

cell membrane The membrane that surrounds the cell, regulating the entry and exit of molecules and ions. Every cell has a cell membrane, and it is also called the plasma membrane.

The membrane has several important roles:

The cell membrane acts as a selectively permeable barrier, preventing some substances from crossing it while permitting other substances to enter and leave the cell.

By regulating transport across it, the cell membrane allows the cell to maintain a more or less constant internal environment. The maintenance of a constant internal environment (known as homeostasis) is a key characteristic of life and will be discussed in detail in [Chapter 40](#).

As the cell's boundary with the outside environment, the cell membrane is important in communicating with adjacent cells and receiving signals from the environment. You will learn about this in [Chapter 7](#).

The cell membrane often has proteins protruding from it that are responsible for binding and adhering to adjacent cells. Thus the cell membrane plays an important structural role and contributes to cell shape.

Cells may be classified as either prokaryotic or eukaryotic

As you saw in [Key Concept 1.1](#), biologists classify all living things into three domains: Archaea, Bacteria, and Eukarya. The organisms in Archaea and Bacteria are collectively called [prokaryotes](#), and they have in common a prokaryotic cell organization. A prokaryotic cell does

not typically have membrane-enclosed internal compartments; in particular, it does not have a nucleus. The first cells were probably similar in organization to those of modern prokaryotes.

prokaryotes Unicellular organisms that do not have nuclei or other membrane-enclosed organelles. Includes Bacteria and Archaea. (Contrast with eukaryotes.)

Eukaryotic cell organization is found in members of the domain Eukarya ([eukaryotes](#)), which includes the protists, plants, fungi, and animals. In contrast to prokaryotic cells, eukaryotic cells contain membrane-enclosed compartments called [organelles](#). The most noticeable organelle is the cell [nucleus](#), where most of the cell's DNA is located and where gene expression begins:

eukaryotes (yew car' ree oats) [Gk. *eu*: true + *karyon*: kernel or nucleus] Organisms whose cells contain their genetic material inside a nucleus. Includes all life other than the viruses, prokaryotic archaea, and bacteria. (Contrast with prokaryotes.)

organelle (or gan el') Any of the membrane-enclosed structures within a eukaryotic cell. Examples include the nucleus, endoplasmic reticulum, and mitochondria.

nucleus (new' klee us) [L. *nux*: kernel or nut] (1) In cells, the centrally located compartment of eukaryotic cells that is bounded by a double membrane and contains the chromosomes. (2) In the brain, an identifiable group of neurons that share common characteristics or functions.

Just as a cell is an enclosed compartment, separating its contents from the surrounding environment, so each organelle provides a compartment that separates molecules and biochemical reactions from the rest of the cell. This “division of labor” provides possibilities for regulation and efficiency that were important in the evolution of complex organisms and helps explain the complexity of eukaryotic cells relative to prokaryotic cells.

5.1 recap

The cell theory is a unifying principle of biology. Cell size is limited in order to maintain a high surface area-to- volume ratio. Both prokaryotic and eukaryotic cells are enclosed within a cell membrane, but prokaryotic cells lack the membrane-enclosed organelles that are found in eukaryotic cells.

learning outcomes

You should be able to:

- List the three tenets of the original cell theory.

- Explain the importance of membranes in cell function.
-

1. How does cell biology embody all the principles of life?
 2. What is the importance of the cell membrane and the membranes that surround organelles?
-

As we mentioned in this section, there are two structural themes in cell architecture: prokaryotic and eukaryotic. We will now turn to the organization of prokaryotic cells.

5.2 Prokaryotic Cells Are the Simplest Cells

With diameters or lengths in the range of 1–10 μm , prokaryotic cells are generally smaller than eukaryotic cells, whose diameters are usually in the range of 10–100 μm . Each individual prokaryote is a single cell, but many types of prokaryotes form chains or small clusters of cells, and some occur in large clusters containing hundreds of cells. In this section we will first consider the features shared by cells in the domains Bacteria and Archaea. Then we will examine structural features that are found in some, but not all, prokaryotes.

focus your learning

All prokaryotic cells contain a cell membrane, nucleoid with DNA, cytoplasm, and ribosomes.

What are the features of prokaryotic cells?

All ***prokaryotic cells** have the same basic structure ([Figure 5.4](#)):

Figure 5.4 A Prokaryotic Cell This electron micrograph and drawing of the bacterium *Pseudomonas aeruginosa* illustrate the typical structures shared by all prokaryotic cells. In addition, this bacterium has a protective outer membrane that is not present in all prokaryotes. The flagellum and capsule are also structures found in some, but not all, prokaryotic cells.

The cell membrane encloses the cell, regulating the traffic of materials into and out of the cell, and separating its interior from the external environment.

The **nucleoid** is a region in the cell where the DNA is located. As we described in [Key Concept 4.1](#), DNA is the hereditary material that controls cell growth, maintenance, and reproduction.

The rest of the material enclosed in the cell membrane is called the **cytoplasm** (cytosol).

Ribosomes are complexes of RNA and proteins in the cytoplasm that are about 25

nanometers (nm) in diameter. They can be visualized only with the electron microscope. They are the sites of protein synthesis, where information coded for in nucleic acids directs the sequential linking of amino acids to form proteins.

nucleoid (new' klee oid) The region that harbors the chromosomes of a prokaryotic cell. Unlike the eukaryotic nucleus, it is not bounded by a membrane.

cytoplasm The contents of the cell, excluding the nucleus.

ribosome A small particle in the cell that is the site of protein synthesis.

The cytoplasm is not static. Rather, the substances in this environment are in constant motion. For example, a typical protein moves around the entire cell within a minute, and it collides with many other molecules along the way. This motion helps ensure that biochemical reactions proceed at rates sufficient to meet the needs of the cell. Although they are structurally less complex than eukaryotic cells, prokaryotic cells are functionally complex, carrying out thousands of biochemical reactions.

Specialized features are found in some prokaryotes

As they evolved, some prokaryotes developed specialized structures that gave them a selective advantage: cells with these structures were better able to survive and reproduce in particular environments than cells lacking them.

CELL WALLS

Most prokaryotes have a [cell wall](#) located outside the cell membrane. The rigid wall supports the cell and determines its shape. The cell walls of most bacteria, but not archaea, contain peptidoglycan, a polymer of amino sugars that is linked at regular intervals to short peptides. Cross-linking among these peptides results in a single giant molecule around the entire cell. In some bacteria, another layer, the **outer membrane** (a polysaccharide-rich phospholipid membrane), encloses the peptidoglycan layer (see [Figure 5.4](#)). Unlike the cell membrane, this outer membrane is not a major barrier to the movement of molecules across it.

cell wall A relatively rigid structure that encloses cells of plants, fungi, many protists, and most prokaryotes, and which gives these cells their shape and limits their expansion in hypotonic media.

Enclosing the cell wall in some bacteria is a slimy layer composed mostly of polysaccharides and referred to as a [capsule](#). In some cases these capsules protect the bacteria from attack by white blood cells in the animals they infect. Capsules also help keep the cells from drying out, and sometimes they help bacteria attach to other cells.

capsule In some prokaryotes, a dense layer of polymers that surrounds the cell wall.

INTERNAL MEMBRANES

Some groups of bacteria—including the cyanobacteria—carry out photosynthesis: they use energy from the sun to convert carbon dioxide and water into carbohydrates. These bacteria have an **internal membrane** system that contains molecules needed for photosynthesis. The development of photosynthesis, which requires membranes, was an important event in the early evolution of life on Earth. Other prokaryotes have internal membrane folds that are attached to

the cell membrane. These folds may function in cell division or in various energy-releasing reactions.

FLAGELLA AND PILI

Some prokaryotes swim by using appendages called **flagella**, which sometimes look like tiny corkscrews (**Figure 5.5A**). In bacteria, the filament of the flagellum is made of a protein called flagellin. (As you will see in **Key Concept 5.3**, the flagella of eukaryotes are quite different in structure, but similar in function.) A complex motor protein spins the bacterial flagellum on its axis like a propeller, driving the cell along. The motor protein is anchored to the cell membrane and, in some bacteria, to the outer membrane of the cell wall (**Figure 5.5B**). We know that the flagella cause the motion of cells because if they are removed, the cells do not move.

flagellum (fla jell' um) (plural: flagella) [L. *flagellum*: whip] Long, whiplike appendage that propels cells. Prokaryotic flagella differ sharply from those found in eukaryotes.

Figure 5.5 Prokaryotic Flagella (A) Flagella contribute to the movement and adhesion of prokaryotic cells. (B) Complex protein ring structures anchored in the cell membrane form a motor unit that rotates the flagellum and propels the cell.

Pili are structures made of protein that project from the surfaces of some types of bacterial cells. These hairlike structures are shorter than flagella and are used for adherence. Conjugative pili (sex pili) help bacteria join to one another to exchange genetic material. Fimbriae are composed of the same proteins as pili but are shorter, and help cells adhere to surfaces such as animal cells, for food and protection.

CYTOSKELETON

The **cytoskeleton** is the collective name for protein filaments that play roles in cell division, cell movement, and in maintaining the shapes of cells. One such protein forms a ring structure that constricts during cell division, whereas another forms helical structures that extend down the lengths of rod-shaped cells, helping maintain their shapes. In the past it was thought that only eukaryotic cells had cytoskeletons (see **Key Concept 5.3**), but more recently, biologists have recognized that cytoskeletal components are also widely distributed among prokaryotes.

cytoskeleton The network of microtubules and microfilaments that gives a eukaryotic cell its

shape and its capacity to arrange its organelles and to move.

5.2 recap

Prokaryotic cells share basic features, including the cell membrane and a region called the nucleoid. The rest of the material enclosed by the cell membrane, including the ribosomes, is called the cytoplasm. Other features, such as cell walls, internal membranes, and flagella, are present in some but not all prokaryotes.

learning outcomes

You should be able to:

- Describe the major features of a prokaryotic cell.
 - Identify specialized features found in some prokaryotic cells.
-
1. What are the structure and function of the following specialized prokaryotic cell features: cell wall, capsule, and flagellum?
 2. What are the chemical compositions of the nucleoid and cytoplasm in a prokaryotic cell?

As we have already noted, the prokaryotic cell is one of two types of cell recognized in cell biology. The other is the eukaryotic cell. Eukaryotic cells are more structurally and functionally complex than prokaryotic cells.

***connect the concepts** In terms of sheer numbers, prokaryotes are the most successful organisms on Earth. As we examine prokaryotic cells in this section, bear in mind that there are vast numbers of prokaryotic species, and that bacteria and archaea are distinguished in numerous ways. These differences, and the vast diversity of organisms in these two domains, will be the subject of [Chapter 26](#).

5.3 Eukaryotic Cells Contain Organelles

You are probably familiar with several types of cells in your body, such as blood cells, skin cells, and brain cells. While these cells have distinctive structures and functions, they and other eukaryotic cells share many features, and it is these common features that we will discuss in this section.

focus your learning

Eukaryotic cells differ from prokaryotic cells in that they contain membrane-bound structures known as organelles.

Each organelle carries out a different specific function that, when combined with others, allows the cell to function as a whole.

Activity 5.3 Eukaryotic Cell Tour www.Life11e.com/ac5.3

Eukaryotic cells generally have lengths or diameters about ten times greater than those of prokaryotes. Like prokaryotic cells, eukaryotic cells have a cell membrane, cytoplasm, and ribosomes. Other structures in eukaryotic cells analogous to those in prokaryotes include a cytoskeleton composed of protein fibers and, outside the cell membrane, an extracellular matrix. But as you learned earlier in this chapter, eukaryotic cells also have compartments within the cytoplasm that are separated by membranes.

Compartmentalization is important to eukaryotic cell function

The membranous compartments of eukaryotic cells are called organelles. All eukaryotic cells have many organelles and structures in common; the most obvious is the cell nucleus. But they also have some differences. For example, many plant cells have chloroplasts that perform photosynthesis. Each type of organelle has a specific role: some organelles have been characterized as factories that make specific products, whereas others are like power plants that take in energy in one form and convert it to a more useful form. These functional roles are defined by the chemical reactions that occur within the organelles. Ion concentrations differ from one organelle to another. For instance, the pH (a reflection of the concentration on H^+) is 7.4 inside the nucleus, but 4.5 (a concentration 1,000 times higher) inside another organelle, the lysosome.

Organelles can be studied by microscopy or isolated for chemical analysis

Cell organelles and structures were first detected by light and then by electron microscopy. The functions of the organelles could sometimes be inferred by observations and experiments, leading, for example, to the hypothesis (later confirmed) that the nucleus contained the genetic material. Later, the use of stains targeted to specific macromolecules allowed cell biologists to determine the chemical compositions of organelles.

Another way to analyze cells is to take them apart in a process called differential centrifugation, or cell fractionation. This process permits cell organelles and other cytoplasmic structures to be separated from each other and examined using chemical methods. Cell fractionation begins with the destruction of the cell membrane, which allows the cytoplasmic components to flow out into a test tube. The various organelles can then be separated from one

another on the basis of size or density ([Figure 5.6](#)). Biochemical analyses can then be done on the isolated organelles. Microscopy and cell fractionation have complemented each other, giving us a more complete picture of the composition and function of each organelle and structure.

Figure 5.6 Cell Fractionation Organelles can be separated from one another after cells are broken open and their contents suspended in an aqueous medium. The medium is placed in a tube and spun in a centrifuge, which rotates about an axis at high speed. Centrifugal forces (measured in multiples of gravity, $\times g$) cause particles to sediment (form a pellet) at the bottom of the tube, which may be collected for biochemical study. Heavier particles sediment at lower speeds (lower centrifugal forces) than lighter particles. By adjusting the speed of centrifugation, researchers can separate and partially purify cellular organelles and large particles such as ribosomes.

Microscopy of eukaryotic cells has revealed that many of the organelles are similar in appearance in each cell type ([Figure 5.7](#)). By comparing [Figures 5.7](#) and [5.4](#) you can see some of the prominent differences between eukaryotic cells and prokaryotic cells.

Cellular structures found in plant but not animal cells include the cell wall and the chloroplasts. Note that the images are two-dimensional “slices,” whereas cells are three-dimensional structures.

Media Clip 5.1 The Inner Life of a Cell www.Life11e.com/mc5.1

Ribosomes are factories for protein synthesis

The ***ribosomes** of prokaryotes and eukaryotes are similar in that both types consist of two different-sized subunits. Eukaryotic ribosomes are somewhat larger than those of prokaryotes, but the structure of prokaryotic ribosomes is better understood. Chemically, ribosomes consist of a special type of RNA called ribosomal RNA (rRNA). Ribosomes also contain more than 50 different protein molecules, which fit together noncovalently, employing forces for protein interaction such as hydrophobic interactions (see [Figure 3.12](#)). Additionally, some of the proteins bind noncovalently to the rRNA.

In prokaryotic cells, ribosomes generally float freely in the cytoplasm. In eukaryotic cells they are found in multiple places: floating freely in the cytoplasm or attached to the surface of the endoplasmic reticulum (a membrane-bound organelle; see below), inside the mitochondria, and inside the chloroplasts in plant cells. In each of these locations, the ribosomes are molecular factories where proteins are synthesized. Although they seem small in comparison with the cells that contain them, by molecular standards ribosomes are huge complexes (about 25 nm in diameter), made up of several dozen different molecules.

Because they lack membranes and are not a compartment, ribosomes are not classified as organelles. Rather, like the cytoskeleton (see below) they are called cell structures.

The nucleus contains most of the genetic

information

As we discussed in [Chapter 4](#), hereditary information is stored in the sequence of nucleotides in DNA molecules. Most of the DNA in eukaryotic cells resides in the nucleus (see [Figure 5.7](#)). Information encoded in the DNA is translated into proteins at the ribosomes (a process we will describe in detail in [Chapter 14](#)).

Most cells have a single nucleus, which is usually the most prominent organelle. The nucleus of a typical animal cell is approximately 5 μm in diameter—substantially larger than many entire prokaryotic cells ([Figure 5.8A](#)). The nucleus has several functions in the cell:

Figure 5.8 The Nucleus, Chromatin, and Chromosomes (A) Chromatin consists of

nuclear DNA and the proteins associated with it. When the cell is not dividing, the chromatin is dispersed throughout the nucleus. This twodimensional image was made using a transmission electron microscope. **(B)** The nuclear envelope has many pores that regulate traffic of large molecules such as RNA and proteins in and out of the nucleus. **(C)** The chromatin in dividing cells becomes highly condensed, so that the individual chromosomes can be seen. This three-dimensional image of isolated metaphase chromosomes was produced using a scanning electron microscope.

It is the location of most of the cell's DNA and the site of DNA replication.

It is the site where gene transcription is turned on or off.

A region within the nucleus, the [nucleolus](#), is where ribosomes begin to be assembled from RNA and proteins.

nucleolus (new klee' oh lus) A small, generally spherical body found within the nucleus of eukaryotic cells. The site of synthesis of ribosomal RNA.

The contents of the nucleus, aside from the nucleolus, are referred to as the nucleoplasm. Similar to the cytoplasm, the nucleoplasm consists of the liquid content of the nucleus and the insoluble molecules suspended within it.

The nucleus is surrounded by an integrated structure composed of two membranes, called the [nuclear envelope](#). This structure separates the genetic material from the cytoplasm. Functionally, it separates DNA transcription (which occurs in the nucleus) from translation (which occurs in the cytoplasm) (see [Key Concept 4.1](#)). The two membranes of the nuclear envelope are perforated by thousands of nuclear pores ([Figure 5.8B](#)), each measuring approximately 9 nm in diameter, which connect the nucleoplasm with the cytoplasm.

nuclear envelope A double membrane that encloses the cell nucleus.

The pores act as “traffic cops,” allowing some molecules to pass into and out of the nucleus and blocking others. This allows the nucleus to regulate its information-processing functions. Small substances, including ions and other molecules with molecular weights of less than 10,000 daltons, move through the pores. But larger molecules, such as most proteins that are made in the cytoplasm, can't get through. In some cases, however, there is a special transport mechanism to get such proteins into the nucleus; you'll learn about this in [Chapter 14](#).

Inside the nucleus, DNA is combined with proteins to form a fibrous complex called [chromatin](#). Chromatin occurs in the form of exceedingly long, thin threads called [chromosomes](#). Different eukaryotic organisms have different numbers of chromosomes (ranging from two in one kind of Australian ant to hundreds in some plants). Prior to cell division, the chromatin becomes tightly compacted and condensed so that the individual chromosomes are visible under a light microscope. This facilitates distribution of the DNA during cell division ([Figure 5.8C](#)).

chromatin The nucleic acid–protein complex that makes up eukaryotic chromosomes.

chromosome (krome' o sowm) [Gk. *kroma*: color + *soma*: body] In bacteria and viruses, the DNA molecule that contains most or all of the genetic information of the cell or virus. In eukaryotes, a structure composed of DNA and proteins that bears part of the genetic information of the cell.

At the inside edge of the nucleus, the chromatin is attached to a protein meshwork, called the nuclear lamina, which is formed by the polymerization of proteins called lamins into long, thin structures called intermediate filaments (see below). The nuclear lamina maintains the shape of the nucleus by its attachment to both the chromatin and the nuclear envelope. On the outside of the nucleus, the outer membrane of the nuclear envelope folds outward into the cytoplasm and is continuous with the membrane of another organelle, the endoplasmic reticulum, which we will discuss next.

The endomembrane system is a group of interrelated organelles

Much of the volume of some eukaryotic cells is taken up by an extensive [endomembrane system](#). This is an interconnected system of membrane-enclosed compartments that are sometimes flattened into sheets and sometimes have other characteristic shapes (see [Figure 5.7](#)). The endomembrane system includes the cell membrane, the nuclear envelope, the endoplasmic reticulum, the Golgi apparatus, and lysosomes, which are derived from the Golgi apparatus. Tiny, membrane-surrounded droplets called vesicles shuttle substances between the various components of the endomembrane system (**Focus: Key Figure 5.9**). In drawings and electron microscope pictures, this system appears static, fixed in space and time. But these depictions are just snapshots; in the living cell, the membranes and the materials they contain are in constant motion. Membrane components have been observed to shift from one organelle to another within the endomembrane system. Thus all these membranes must be functionally related.

endomembrane system A system of intracellular membranes that exchange material with one another, consisting of the Golgi apparatus, endoplasmic reticulum, and lysosomes when present.

focus: key figure

Figure 5.9 The Endomembrane System Membranes of the nucleus, endoplasmic reticulum, and Golgi apparatus form a network connected by vesicles.

Q: What processes in the endomembrane system are mediated by vesicles?

ENDOPLASMIC RETICULUM

Electron micrographs of eukaryotic cells reveal networks of interconnected membranes branching throughout the cytoplasm, forming tubes and flattened sacs. These membranes are collectively called the **endoplasmic reticulum**, or **ER**. The interior compartment of the ER, referred to as the **lumen**, is separate and distinct from the surrounding cytoplasm (see [Figure 5.9](#)). The ER can enclose up to 10 percent of the interior volume of the cell, and its folds result in a surface area many times greater than that of the cell membrane. There are two types of endoplasmic reticulum, the so-called rough and smooth.

endoplasmic reticulum (ER) [Gk. *endo*: within + L. *reticulum*: net] A system of membranous tubes and flattened sacs found in the cytoplasm of eukaryotes. Exists in two forms: rough ER, studded with ribosomes; and smooth ER, lacking ribosomes.

ER See endoplasmic reticulum.

Rough endoplasmic reticulum (RER) is called “rough” because of the many ribosomes attached to the outer surface of the membrane, giving it a “rough” appearance in electron microscopy (see [Figure 5.7](#)). The bound ribosomes are actively involved in protein synthesis, but that is not the entire story:

rough endoplasmic reticulum (RER) The portion of the endoplasmic reticulum whose outer surface has attached ribosomes. (Contrast with smooth endoplasmic reticulum.)

The RER receives into its lumen certain newly synthesized proteins (including proteins destined for lysosomes, the cell membrane, and export from the cell), segregating them away from the cytoplasm. The RER also participates in transporting these proteins to other locations in the cell.

While inside the RER, proteins can be chemically modified to alter their functions and to “tag” them for delivery to specific cellular destinations.

Proteins are shipped to destinations elsewhere in the cell enclosed within vesicles that pinch off from the RER.

Most membrane-bound proteins are made in the RER.

A protein enters the lumen of the RER through a pore as it is synthesized. As with a protein passing through a nuclear pore, there is a special transport mechanism to get proteins into the ER, which you’ll learn about in [Chapter 14](#). Once in the lumen of the RER, proteins undergo several changes, including the formation of disulfide bridges and folding into their tertiary structures (see [Figure 3.5](#)).

Some proteins are covalently linked to carbohydrate groups in the RER, thus becoming glycoproteins. In the case of proteins directed to the lysosomes, the carbohydrate groups are part of an “addressing” system that ensures that the right proteins are directed to those organelles. This addressing system is very important because the enzymes within the lysosomes are some of the most destructive the cell makes. Were they not properly addressed and contained, they could destroy the cell.

The **smooth endoplasmic reticulum (SER)** lacks ribosomes and is more tubular (and less ; like flattened sacs) than the RER, but it shows ' continuity with portions of the RER (see [Figure 5.9](#)). Certain proteins that are synthesized in the RER are chemically modified within the lumen of the ***SER**. The SER has four other important roles:

smooth endoplasmic reticulum (SER) Portion of the endoplasmic reticulum that lacks ribosomes and has a tubular appearance. (Contrast with rough endoplasmic reticulum.)

- . It is responsible for the chemical modification of small molecules taken in by the cell that may be toxic to the cell. These modifications make the targeted molecules more polar, so they are more water-soluble and easily removed.
- . It is the site for glycogen degradation in animal cells. We will discuss this important process in [Chapter 9](#).
- . It is the site where lipids and steroids are synthesized, as well as some polysaccharides in plant cells.
- . It stores calcium ions, which when released trigger a number of cell responses.

Cells that synthesize a lot of protein for export are usually packed with RER. Examples include glandular cells that secrete digestive enzymes and white blood cells that secrete antibodies. In contrast, cells that carry out less protein synthesis (such as storage cells) contain less RER. Liver cells, which modify molecules (including toxins) that enter the body from the digestive system, have abundant SER.

GOLGI APPARATUS

The **Golgi apparatus** (or Golgi complex, or just Golgi) is another part of the diverse, dynamic, and extensive endomembrane system (see [Figure 5.9](#)). This structure was named after its discoverer, Camillo Golgi. Its appearance varies, but it almost always consists of two components: flattened membranous sacs called cisternae (singular cisterna) that are piled up like saucers, and small membrane-enclosed vesicles. The entire apparatus is about 1 μm long.

Golgi apparatus (goal' jee) A system of concentrically folded membranes found in the cytoplasm of eukaryotic cells; functions in secretion from the cell by exocytosis.

The Golgi apparatus has several roles:

It receives protein-containing vesicles from the RER.

It modifies, concentrates, packages, and sorts proteins before they are sent to their cellular or extracellular destinations.

It adds carbohydrates to proteins and modifies other carbohydrates that were attached to proteins in the RER.

It is where some polysaccharides for the plant cell wall are synthesized.

The cisternae of the Golgi apparatus have three functionally distinct regions:

- . The *cis* region lies nearest to the nucleus or a patch of RER.
- . The *trans* region lies closest to the cell membrane.
- . The *medial* region lies in between (see [Figure 5.9](#)).

The terms *cis*, *trans*, and *medial* derive from Latin words meaning, respectively, “on the same side,” “on the opposite side,” and “in the middle.” These three parts of the Golgi apparatus contain different enzymes and perform different functions.

Protein-containing vesicles from the RER fuse with the *cis* membrane of the Golgi apparatus, releasing their cargo into the lumen of the Golgi apparatus cisterna. Other vesicles may move between the cisternae, transporting proteins, and it appears that some proteins move from one cisterna to the next through tiny channels. Vesicles budding off from the *trans* region carry their contents away from the Golgi apparatus. These vesicles go to the cell membrane or to the lysosome, another organelle in the endomembrane system.

ER → *cis*-Golgi → *medial*-Golgi → *trans*-Golgi ↘ lysosome ↗ cell membrane

ER → *cis*-Golgi → *medial*-Golgi → *trans*-Golgi ↗ cell membrane ↘ lysosome

How do the vesicles in this system recognize their targets for fusion? In other words, when a vesicle buds off from the ER, how does it “know” to fuse with the *cis*-Golgi membrane? The answer lies in proteins on both membranes appropriately called SNARES. Pairs of SNARES are complementary—that is, they bind to one another like a lock and key. So the SNARE on the ER surface that forms a vesicle can bind to a SNARE on the *cis*-Golgi.

LYSOSOMES

The [primary lysosomes](#) originate from the Golgi apparatus. They contain digestive enzymes and are the sites where macromolecules—proteins, polysaccharides, nucleic acids, and lipids—are hydrolyzed into their monomers (see [Figure 3.4](#)).

primary lysosomes A lysosome before fusion with an endosome.

Lysosomes are about 1µm in diameter, are surrounded by a single membrane, and have a densely staining, featureless interior ([Figure 5.10](#)). There may be dozens of lysosomes in a cell, depending on its needs.

Figure 5.10 Lysosomes Isolate Digestive Enzymes from the Cytoplasm

Lysosomes are sites for the hydrolysis of material taken into the cell by phagocytosis. Discarded components exit the cell by exocytosis.

Activity 5.4 Lysosomal Digestion www.Life11e.com/ac5.4

Lysosomes are cellular “disposals,” compartments for the breakdown of food, other cells, or foreign objects that are taken up by the cell. These materials enter the cell by a process called **phagocytosis** (*phago*, “eat,” + *cytosis*, “cellular”). In this process, a pocket forms in the cell membrane and then deepens and encloses material from outside the cell. The pocket becomes a small vesicle called a phagosome, containing food or other material, which breaks free of the cell membrane to move into the cytoplasm. The phagosome fuses with a primary lysosome to form a **secondary lysosome**, where digestion occurs.

phagocytosis The process by which a cell uses its cell membrane to enclose and engulf a macromolecule or particle in the extracellular environment.

secondary lysosome Membrane-enclosed organelle formed by the fusion of a primary lysosome with a phagosome, in which macromolecules taken up by phagocytosis are hydrolyzed into their monomers. (Contrast with lysosome.)

The effect of this fusion is rather like children devouring Halloween candy: the enzymes in the secondary lysosome quickly hydrolyze the food particles. These reactions are enhanced by the acidity of the lysosome’s interior, where the pH is lower than in the surrounding cytoplasm. The products of digestion pass through the membrane of the lysosome, providing energy and raw materials for other cellular processes. For example, a protease might hydrolyze proteins to amino acids, which are released to the cytoplasm for reassembly into other proteins. The “used” secondary lysosome, now containing undigested particles, then moves to the cell membrane, fuses with it, and releases the undigested contents to the environment, a process called **exocytosis**.

exocytosis A process by which a vesicle within a cell fuses with the plasma membrane and releases its contents to the outside. (Contrast with endocytosis.)

Phagocytes (see [Key Concept 41.1](#)) are specialized cells that have an essential role in taking up and breaking down materials; they are found in nearly all animals and many protists. You will encounter them and their activities again at many places in this book, but at this point one example suffices: in the human liver and spleen, phagocytes digest approximately 10 billion aged or damaged blood cells each day! The digestion products are then used to make new cells to replace those that are digested.

Lysosomes are active even in cells that do not perform phagocytosis. Cells are dynamic systems; some cell components are continually being broken down and replaced by new ones. The programmed destruction of cell components is called **autophagy**, and lysosomes are where the cell breaks down its own materials. With the proper signal, lysosomes can engulf entire organelles, hydrolyzing their constituents.

autophagy The programmed destruction of a cell’s components.

How important is autophagy? An entire class of human diseases called lysosomal storage

diseases are caused by the failure of lysosomes to digest specific cellular components; these diseases are invariably harmful or fatal. An example is Tay-Sachs disease, in which a particular lipid called a ganglioside is not broken down in the lysosomes and instead accumulates in brain cells. In the most common form of this disease, a baby starts exhibiting neurological symptoms and becomes blind, deaf, and unable to swallow after 6 months of age. Death occurs before age 4.

Plant cells do not appear to contain lysosomes, but the vacuole of a plant cell (which we will describe below) may function in an equivalent capacity because it, like lysosomes, contains many digestive enzymes.

Some organelles transform energy

A cell requires energy to make the molecules it needs for activities such as growth, reproduction, responsiveness, and movement. Energy is harvested from fuel molecules in the mitochondria (found in all eukaryotic cells) and from sunlight in the chloroplasts of plant cells. In contrast, energy transformations in prokaryotic cells are associated with enzymes attached to the inner surface of the cell membrane or to extensions of the cell membrane that protrude into the cytoplasm.

MITOCHONDRIA

In eukaryotic cells, the breakdown of energy-rich molecules such as glucose begins in the cytoplasm. The molecules that result from this partial degradation enter the **mitochondria** (singular *mitochondrion*), whose primary function is to harvest the chemical energy of those molecules in a form that the cell can use, namely the energy-rich molecule ATP (adenosine triphosphate) (see [Key Concept 8.2](#)). The production of ATP in the mitochondria, using fuel molecules and molecular oxygen (O_2), is called **cellular respiration**.

mitochondria (my' toe kon' dree uh) (singular: mitochondrion) [Gk. *mitos*: thread + *chondros*: grain] Energy-generating organelles in eukaryotic cells that contain the enzymes of the citric acid cycle, the respiratory chain, and oxidative phosphorylation.

cellular respiration The catabolic pathways by which electrons are removed from various molecules and passed through intermediate electron carriers to O_2 , generating H_2O and releasing energy.

Typical mitochondria are somewhat less than $1.5\ \mu m$ in diameter and are $2\text{--}8\ \mu m$ in length—about the size of many bacteria. They can reproduce and divide independently of the central nucleus. The number of mitochondria per cell ranges from one large organelle in some unicellular protists to a few hundred thousand in large egg cells. An average human liver cell contains more than 1,000 mitochondria. Cells that are active in movement and growth require the most chemical energy, and these tend to have the most mitochondria per unit of volume.

Mitochondria have two membranes. The outer membrane is smooth and protective, and it offers little resistance to the movement of substances into and out of the organelle. Immediately inside the outer membrane is an inner membrane, which folds inward in many places and thus has a surface area much greater than that of the outer membrane ([Figure 5.11](#)). The folds tend to be quite regular, giving rise to shelflike structures called cristae. The inner membrane exerts much more control over what enters and leaves the space it encloses than does the outer membrane. Embedded in the inner mitochondrial membrane are many large protein complexes that participate in cellular respiration.

Figure 5.11 A Mitochondrion Converts Energy from Fuel Molecules into ATP The electron micrograph is a two-dimensional slice through a three-dimensional organelle. As the drawing emphasizes, the cristae are extensions of the inner mitochondrial membrane.

Q: What kinds of human cells would you expect to have a lot of mitochondria?

The space enclosed by the inner membrane is referred to as the mitochondrial matrix. In addition to many enzymes, the matrix contains ribosomes and DNA that are used to make some of the proteins needed for cellular respiration. As we will discuss later in this chapter, it is likely that this DNA is the remnant of a larger, complete chromosome from a prokaryote that may have been the mitochondrion's progenitor. In [Chapter 9](#) we will discuss how the different parts of the mitochondrion work together in cellular respiration.

PLASTIDS

One class of organelles—the plastids—is present only in the cells of plants and certain protists. Like mitochondria, plastids can divide independently of the cell nucleus and probably evolved from independent prokaryotes. There are several types of plastids, with different functions.

Just as melanosomes are a compartment for pigment in animal cells (see the chapter opening), so are **chloroplasts**, which contain the green pigment chlorophyll and are the sites of photosynthesis (**Figure 5.12**). In photosynthesis, light energy is converted into the chemical energy of bonds between atoms. The molecules formed by photosynthesis provide food for the photosynthetic organism and for other organisms that eat it. Directly or indirectly, photosynthesis is the energy source for most of the living world.

chloroplast [Gk. *kloros*: green + *plast*: a particle] An organelle bounded by a double membrane containing the enzymes and pigments that perform photosynthesis. Chloroplasts occur only in eukaryotes.

Figure 5.12 Chloroplasts Feed the World The electron micrographs show chloroplasts from a leaf of corn. Chloroplasts are large compared with mitochondria and contain extensive networks of thylakoid membranes. These membranes contain the green pigment chlorophyll, and are the sites where light energy is converted into chemical energy for the synthesis of carbohydrates from CO_2 and H_2O .

Like a mitochondrion, a chloroplast is surrounded by two membranes. In addition, there is a series of internal membranes whose structure and arrangement vary from one group of photosynthetic organisms to another. Here we concentrate on the chloroplasts of the flowering plants.

The internal membranes of chloroplasts look like stacks of flat, hollow pita bread. Each stack is called a granum (plural grana) and the pita bread-like compartments are called **thylakoids** (see [Figure 5.12](#)). Thylakoid lipids are distinctive: only 10 percent are phospholipids, whereas the rest are galactose-substituted diglycerides and sulfolipids. Because of the abundance of chloroplasts, these are the most abundant lipids in the biosphere.

thylakoid (thigh' la koid) [Gk. *thylakos*: sack or pouch] A flattened sac within a chloroplast. Thylakoid membranes contain all of the chlorophyll in a plant, in addition to the electron carriers of photophosphorylation. Thylakoids stack to form grana.

In addition to lipids and proteins, the membranes of the thylakoids contain chlorophyll and other pigments that harvest light energy for photosynthesis (we will see how they do this in [Key Concept 10.2](#)). The thylakoids of one granum may be connected to those of other grana, making the interior of the chloroplast a highly developed network of membranes, much like the ER.

The fluid in which the grana are suspended is called the stroma. Like the mitochondrial matrix, the chloroplast stroma contains ribosomes and DNA, which are used to synthesize some, but not all, of the proteins that make up the chloroplast.

Other types of plastids, such as chromoplasts and leucoplasts, have functions different from those of chloroplasts. Chromoplasts make and store red, yellow, and orange pigments, especially in flowers and fruits—again, just as the melanocytes in the opening story store pigment.

Leucoplasts are storage organelles that do not contain pigments. An amyloplast is a leucoplast that stores starch.

There are several other membrane-enclosed organelles

There are several other organelles whose boundary membranes separate their specialized chemical reactions and contents from the rest of the cytoplasm: peroxisomes, glyoxysomes, and vacuoles.

Peroxisomes are organelles that accumulate toxic peroxides, such as hydrogen peroxide (H_2O_2), that occur as by-products of some biochemical reactions. These peroxides are safely broken down inside the peroxisomes without mixing with other parts of the cell.

peroxisome An organelle that houses reactions in which toxic peroxides are formed and then converted to water.

Peroxisomes are small organelles, about 0.2–1.7 μm in diameter. They have a single membrane and a granular interior containing specialized enzymes. Peroxisomes are found in at least some of the cells of almost every eukaryotic species.

As with lysosomes, there are rare inherited diseases in humans that involve peroxisomes. In Zellweger syndrome there is a defect in peroxisome assembly, and affected infants are born without peroxisomes. As you can imagine, a consequence of this is the accumulation of toxic peroxides, and the infants seldom live beyond 1 year of age.

Glyoxysomes are similar to peroxisomes and are found only in plants. They are most abundant in young plants and are the locations where stored lipids are converted into carbohydrates for transport to growing cells.

glyoxysome (gly ox' ee soam) An organelle found in plants, in which stored lipids are converted to carbohydrates.

Vacuoles occur in many eukaryotic cells but particularly those of plants, fungi, and protists. They arise from the ER or Golgi apparatus. Plant vacuoles ([Figure 5.13](#)) have several functions:

vacuole (vac' yew ole) Membrane-enclosed organelle in plant cells that can function for storage, water concentration for turgor, or hydrolysis of stored macromolecules.

Figure 5.13 Vacuoles in Plant Cells Are Usually Large The large central vacuole in this cell is typical of mature plant cells.

Structure: In many plant cells, vacuoles take up more than 90 percent of the cell volume and grow as the cell grows. The presence of dissolved substances in the vacuole causes water to enter it from the cytoplasm, making the vacuole swell like a balloon. A mature plant cell does not swell when the vacuole fills with water, since it has a rigid cell wall. Instead, it stiffens from the increase in water pressure (called turgor), and this supports the plant body (see [Figure 6.10](#)).

Reproduction: Vacuoles contain some of the pigments (especially blue and pink ones) in the petals and fruits of flowering plants. These pigments—the anthocyanins—are visual cues that help attract animals that assist in pollination or seed dispersal.

Digestion: In some plants, the vacuoles in seeds contain enzymes that hydrolyze stored proteins into monomers. During seed germination, the monomers are used as food by the developing plant seedlings.

Storage: In addition to storing water, vacuoles store toxic molecules and waste products. Because they are poisonous or distasteful, these stored materials deter some animals from eating the plants and may thus contribute to plant defense and survival. An example is tannins, a class of polyphenols that are made in many plants and may be familiar to you as the aftertaste in tea and red wine. Their bitter taste deters predators, and their dark color acts like animal melanin to protect the plant from ultraviolet light damage. Tannins are made in the chloroplast and end up in the vacuole. A newly discovered organelle, appropriately named the tannosome, contains tannins (**Investigating Life: Discovering a New Organelle, the**

Tannosome).

So far we have discussed numerous membrane-enclosed organelles. Now we will turn to a group of cytoplasmic structures without membranes.

investigatinglife Discovering a New Organelle, the Tannosome

experiment

Original Paper: Brillouet, J.-M. et al. 2013. The tannosome is an organelle forming condensed tannins in the chlorophyllous organs of *Tracheophyta*. *Annals of Botany* 112: 1003–1014.

Through a series of investigations involving microscopy, cell fractionation, and chemical analysis, biologists discovered that plant tannins are compartmentalized in a heretofore undiscovered structure, the tannosome.

QUESTION ▶ Are pigments compartmentalized in all types of cells?

1 Examine plants that make tannins (e.g., grapevines).

METHOD

2 Examine cells in electron microscope.

3 Stain with dye specific for tannins and examine in light microscope.

4 Separate organelles using cell fractionation.

5 Analyze the chemistry of the organelles for tannins.

RESULTS

Tannin grains observed in chloroplast.

Tannins inside organelles

Tannin organelles separate from chloroplasts

Tannins identified

CONCLUSION ▶ Tannins are present in an organelle that begins in the chloroplast.

work with the data

The team of biologists and chemists (Brillouet et al., 2013) at the French National Institute for Agricultural Research, led by Geneviève Conejero, sought to investigate the cellular basis of tannin formation. It was well known from electron micrographs that these pigments accumulate in vacuoles, but how they got there was not established. The team used a combination of microscopy (light and electron) (see Figure 5.3), cell fractionation (see Figure 5.6), and chemical analysis to show that tannins are formed in discrete vesicles, which the researchers named tannosomes.

QUESTIONS

1. Plant organs rich in tannins were examined by electron microscopy. Representative photographs are shown in **Figure A**. What do these images indicate about the origin and final resting spot of tannins in the cell? Based on what you know of vesicle trafficking in the cell, how do you think the tannins get from the chloroplast to the vacuole?

Figure A

Chloroplast with tannin granules

Vacuole with tannin vesicles

2. The scientists used specific dyes targeted to chlorophyll and tannins and examined slices of plant tissues by light microscopy. **Figure B** shows the results. What can you conclude about the subcellular origin of tannins, and how does your answer relate to your answer to Question 1?

Figure B

Staining of plant cell for chlorophyll

Staining of plant cell for tannins

3. Cell fractionation was used to try to isolate tannin-containing structures separate from chloroplasts. In a very dense (72%), syrupy sucrose medium, fractionated cell contents showed two membrane-bound fractions (see the experiment). Both were examined by microscopy for tannin staining, and the contents were analyzed for chlorophyll and tannins. The results are shown in the table. What can you conclude about the tannin compartment?

	Upper fraction	Lower fraction
Staining for tannins	No	Yes
Staining for chlorophyll	Yes	Yes
Chemical analysis for tannins	No	Yes

A similar **work with the data** exercise may be assigned in **LaunchPad**.

and movement

Cell shapes can sometimes change, and there appear to be rapid movements of structures inside cells. These phenomena involve a meshwork of rods within cells that can be seen in electron microscopy. Experimentation showed that this meshwork—called the cytoskeleton—fills several important roles:

It supports the cell and maintains its shape.

It holds cell organelles and other particles in position within the cell.

It moves organelles and other particles around in the cell.

It is involved with movements of the cytoplasm, called cytoplasmic streaming.

It interacts with extracellular structures, helping anchor the cell in place.

The cytoskeleton is important in cell structure

There are three components of the eukaryotic cytoskeleton: microfilaments (smallest diameter), intermediate filaments, and microtubules (largest diameter). These filaments have very different functions.

MICROFILAMENTS

Microfilaments can exist as single filaments, in bundles, or in networks. They are about 7 nm in diameter and up to several micrometers long. Microfilaments have two major roles:

microfilament In eukaryotic cells, a fibrous structure made up of actin monomers. Microfilaments play roles in the cytoskeleton, in cell movement, and in muscle contraction.

- . They help the entire cell or parts of the cell move.
- . They determine and stabilize cell shape.

Microfilaments are assembled from monomers of **actin**, a protein that exists in several forms and has many functions, especially in animals. The actin found in microfilaments (which are also known as ***actin filaments**) has distinct ends, designated “plus” and “minus.” These ends permit actin monomers to interact with one another to form long, double helical chains (**Figure 5.14A**). Within cells, the polymerization of actin into microfilaments is reversible, and the microfilaments can disappear from cells by breaking down into monomers of free actin. Special actin-binding proteins mediate these processes.

actin [Gk. *aktis*: ray] A protein that makes up the cytoskeletal microfilaments in eukaryotic cells and is one of the two contractile proteins in muscle. (See *also* myosin.)

Figure 5.14 The Cytoskeleton Three highly visible and important structural components of the cytoskeleton are shown here in detail. The photographs are all of the same cell, treated with different fluorescent antibodies that detect microfilaments **(A)**, intermediate filaments **(B)**, or microtubules **(C)**. These structures maintain and reinforce cell shape and contribute to cell movement. The position of the cell's nucleus

is near the center of the photos.

In non-muscle cells, actin filaments are associated with localized changes in cell shape. For example, microfilaments are involved in the flowing movement of the cytoplasm called cytoplasmic streaming, in amoeboid movement, and in the “pinching” contractions that divide an animal cell into two daughter cells. Microfilaments are also involved in the formation of cellular extensions called pseudopodia (*pseudo*, “false,” + *podia*, “feet”) that enable some cells to move ([Figure 5.15](#)). As you will see in [Key Concept 41.3](#), cells of the immune system must move toward other cells during the immune response.

Figure 5.15 Microfilaments and Cell Movements Microfilaments mediate the movement of whole cells (as illustrated here for amoeboid movement), as well as the movement of cytoplasm within a cell.

In some cell types, microfilaments form a meshwork just inside the cell membrane. Actin-binding proteins then cross-link the microfilaments to form a rigid netlike structure that supports the cell. For example, microfilaments support the tiny microvilli that line the human intestine, giving it a larger surface area through which to absorb nutrients ([Figure 5.16](#)).

Figure 5.16 Microfilaments for Support Cells that line the intestine are folded into tiny projections called microvilli, which are supported by microfilaments. The microfilaments interact with intermediate filaments at the base of each microvillus. Microvilli increase the surface area of a cell, facilitating its absorption of small molecules.

INTERMEDIATE FILAMENTS

There are at least 50 different kinds of [intermediate filaments](#), many of them specific to a few cell types. They generally fall into six molecular classes (based on amino acid sequence) that share the same general structure. One of these classes consists of fibrous proteins of the keratin family, which also includes the proteins that make up hair and fingernails. Intermediate filaments are tough, ropelike protein structures 8–12 nm in diameter ([Figure 5.14B](#)). They are more permanent than the other two types in that they do not continually form and re-form, as the microtubules and microfilaments do.

intermediate filaments A part of the cytoskeleton that includes filaments intermediate in diameter between microtubules and microfilaments.

Intermediate filaments have two major structural functions:

- They anchor cell structures in place. In some cells, intermediate filaments radiate from the nuclear envelope and help maintain the positions of the nucleus and other organelles in the cell. The lamins of the nuclear lamina are intermediate filaments. Other kinds of intermediate

filaments help hold in place the complex apparatus of microfilaments in the microvilli of intestinal cells (see [Figure 5.16](#)).

- . They resist tension. For example, they maintain rigidity in body surface tissues by stretching through the cytoplasm and connecting specialized membrane structures called desmosomes (see [Figure 6.7](#)).

MICROTUBULES

The largest-diameter components of the cytoskeletal system, **microtubules**, are long, hollow, unbranched cylinders about 25 nm in diameter and up to several micrometers long.

Microtubules have two roles in the cell:

microtubules Tubular structures found in centrioles, spindle apparatus, cilia, flagella, and cytoskeleton of eukaryotic cells. These tubules play roles in the motion and maintenance of shape of eukaryotic cells.

- . They form a rigid internal skeleton for some cells.
- . They act as a framework along which motor proteins can move structures within the cell.

Microtubules are assembled from dimers—two similar molecules in a complex—of the protein tubulin, called α -tubulin and β -tubulin. Thirteen chains of **tubulin** doublets surround the central cavity of the microtubule ([Figure 5.14C](#); see also [Figure 5.17B](#)).

tubulin A protein that polymerizes to form microtubules.

As in microfilaments, the two ends of a microtubule are different: one is designated the “plus” end and the other the “minus” end. Tubulin dimers can be rapidly added or subtracted, mainly at the plus end, lengthening or shortening the microtubule.

Many microtubules appear to radiate from a region of the cell called the microtubule organizing center. Tubulin polymerization results in a rigid structure, and tubulin depolymerization leads to its collapse.

The capacity to change length rapidly makes microtubules dynamic structures: they are readily adapted for new purposes in the cell. For example, by disassembly and reassembly, microtubules can move to new parts of the cell and assemble new structures needed for cell division. Microtubules from all eukaryotes have this dynamic property, indicating that it is evolutionarily advantageous over a static, unchanging structure.

In plants, microtubules act as a framework for the assembly of cellulose and help orient the cellulose fibers of the cell wall (see [Figure 3.18](#)). Electron micrographs of plants frequently show microtubules lying just inside the cell membranes of cells that are forming or extending their cell walls. If the orientation of these microtubules is altered experimentally, it leads to a similar change in the cell wall and a new shape for the cell.

Microtubules serve as tracks for motor proteins, specialized molecules that use cellular energy to change their shapes and move. Motor proteins bind to and move along the microtubules, carrying materials from one part of the cell to another. Microtubules are also essential in distributing chromosomes to daughter cells during cell division. Because of this,

drugs such as vincristine and taxol, which disrupt microtubule dynamics, also disrupt cell division. These drugs are useful for treating cancer, where cell division is excessive.

CILIA AND FLAGELLA

Microtubules and their associated proteins line the interior of certain movable appendages on eukaryotic cells: the **cilia** (**Figure 5.17A**) and flagella. Many cells have one or the other of these appendages, which form from projections of the cell membrane:

cilia (sil' ee ah) (singular: cilium) [L. eyelashes] Hairlike organelle used for locomotion by many unicellular organisms and for moving water and mucus by many multicellular organisms. Generally shorter than flagella.

Figure 5.17 Cilia (A) This unicellular eukaryotic organism (a ciliate protist) can coordinate the beating of its cilia, allowing rapid movement. (B) A cross section of a single cilium shows the arrangement of microtubules and other proteins.

Cilia are only 0.25 μm in length. They occur by the hundreds on individual cells and move stiffly to either propel the cell (for example, in protists) or to move fluid over a stationary cell (as in the human respiratory system).

Flagella are longer—100 to 200 μm—and occur singly or in pairs. They can push or pull a cell through its aqueous environment.

In cross section, a typical cilium or eukaryotic flagellum is surrounded by the cell membrane and contains a “9 + 2” array of microtubules. As **Figure 5.17B** shows, nine fused pairs of microtubules form an outer cylinder, and one pair of unfused microtubules runs up the center. Each doublet is connected to the center of the structure by a radial spoke. This structure is essential to the bending motion of both cilia and flagella. How does this bending occur?

The motion of cilia and flagella results from the sliding of the microtubule doublets past one another. This sliding is driven by the motor protein dynein, which, like other motor proteins, works by undergoing reversible shape changes that require chemical energy. Dynein molecules bind between two neighboring microtubule pairs, and as the dynein molecules change shape, the pairs move past one another (**Figure 5.18**). Another protein, nexin, cross-links the pairs and appears to limit how far the doublets can slide. This causes the cilium or flagellum to bend.

Figure 5.18 Motor Protein Moves Microtubules in Cilia and Flagella A motor protein, dynein, causes microtubule doublets to slide past one another. In a flagellum or cilium, anchorage of the microtubule doublets to one another results in bending.

Q: In some people, the nexin links are absent and microtubule doublets are not attached to one another. What do you think the consequences of this would be?

Other motor proteins, including kinesin, carry protein-laden vesicles or other organelles from one part of the cell to another ([Figure 5.19](#)). These proteins bind to the organelle and “walk” it along a microtubule by a repeated series of shape changes. Recall that ***microtubules** are directional, with a plus end where there is a net addition of tubulin and a minus end where there is removal. Cytoplasmic dynein (which has a different role than the one found in cilia and flagella) moves organelles attached to it toward the minus end, whereas kinesin moves them toward the plus end (see [Figure 5.14](#)). The ability of microtubules to carry vesicles is used by some fish and amphibians to avoid predators. Motor proteins carrying pigment vesicles aggregate them in the center of the cell in response to environmental or nervous system stimuli. This makes the animal appear lighter. When the stimuli are removed, other motor proteins move the vesicles along microtubules to a more even distribution, restoring a darker hue.

(B)

Figure 5.19 A Motor Protein Pulls Vesicles along Microtubules (A) Kinesin delivers vesicles to various parts of the cell by moving along microtubule "railroad tracks." (B) A vesicle is pulled by kinesin along a microtubule in the protist *Dictyostelium*. The time sequence, with half-second intervals, is shown by the color changes from purple to blue.

Biologists can manipulate living systems to establish cause and effect

How do we know that the structural fibers of the cytoskeleton can achieve all these dynamic functions? We can observe an individual structure under the microscope, and we can observe the functions of living cells that contain that structure. These observations may suggest that the structure carries out a particular function, but mere correlation does not show cause and effect. For example, light microscopy of living cells reveals that the cytoplasm is actively streaming around the cell, and that cytoplasm flows into an extended portion of an amoeboid cell during movement. The observed presence of cytoskeletal components *suggests, but does not prove*, their role in this process. Science seeks to show the specific links that relate one process, A, to a function, B. In cell biology, two approaches are often used to show that a structure or process A causes function B:

- **Inhibition:** Use a drug that inhibits A and see if B still occurs. If it does not, then A is probably a causative factor for B. [Figure 5.20](#) shows an experiment with such a drug (an inhibitor) that demonstrates cause and effect in the case of the cytoskeleton and cell movement.

- **Mutation:** Examine a cell that lacks the gene (or genes) for A and see if B still occurs. If it does not, then A is probably a causative factor for B. [Part Four](#) of this book will describe many experiments using this genetic approach.

5.3 recap

The hallmark of eukaryotic cells is compartmentalization. Membrane-enclosed organelles process information, transform energy, form internal compartments for transporting proteins, and carry out intracellular digestion. An internal cytoskeleton plays several structural roles.

learning outcomes

You should be able to:

- Distinguish between prokaryotes and eukaryotes.
- Compare the sizes, structures, typical cell numbers, and roles of subcellular structures.
- Trace the path of a molecule as it moves between organelles in a eukaryotic cell.

1. What are the major differences between prokaryotic cells and eukaryotic cell?
2. Through how many membranes would a molecule have to pass in moving (a) from the interior (stroma) of a chloroplast to the interior (matrix) of a mitochondrion? (b) From the interior of a lysosome to the outside of a cell? (c) From one ribosome to another?
3. The drug vincristine is used to treat many cancers. It appears to work by causing microtubules to depolymerize. Vincristine use has many side effects, including loss of dividing cells and nerve problems. Explain why this might be so.
4. The movements of newly synthesized proteins can be followed through cells using a “pulse-chase” experiment. During synthesis, proteins are tagged with a radioactive isotope (the “pulse”), then the cells are allowed to process the proteins for varying periods of time. The locations of the radioactive proteins are then determined by isolating cell organelles and quantifying their levels of radioactivity. What would be the expected pathway for (a) a lysosomal enzyme and (b) a protein that is released from the cell?

All cells interact with their environments. Many eukaryotic cells are parts of multicellular organisms and must closely coordinate their activities with other cells. The cell membrane plays a crucial role in these interactions, but other structures outside that membrane are involved as well.

***connect the concepts** As discussed in [Key Concept 14.5](#), the ribosome is the molecular workbench where mRNA is translated into protein.

***connect the concepts** Regulating muscle contraction is one of the important roles played by the calcium ions stored by the SER. See [Key Concept 47.1](#).

***connect the concepts** Perhaps the most dramatic role of microtubules is in the process of chromosome movement during cell division. See [Key Concept 11.3](#).

***connect the concepts** connect the concepts In animal muscle cells, actin filaments are associated with another protein, the “motor protein” myosin, and the interactions of these two proteins account for the contraction of muscles, as described in [Key Concept 47.1](#).

5.4 Extracellular Structures Have Important Roles

Although the cell membrane is the functional barrier between the inside and the outside of a cell, many structures are produced by cells and secreted to the outside of the cell membrane, where they play essential roles in protecting, supporting, or attaching cells to each other. Because they are outside the cell membrane, these structures are said to be extracellular. The peptidoglycan cell wall of bacteria is an example of an extracellular structure (see [Figure 5.4](#)). In eukaryotes, other extracellular structures—the cell walls of plants and the extracellular matrices found between the cells of animals—play similar roles. Each of these structures is made up of two main components: a prominent fibrous macromolecule and a gel-like medium in which the fibers are embedded.

focus your learning

Extracellular structures are important for protection, support, and interacting with other cells.

What is the plant cell wall?

The plant cell wall is a semirigid structure outside the cell membrane ([Figure 5.21](#)). We will consider the structure and role of the cell wall in more detail in [Chapter 33](#). For now, we note that it consists of cellulose fibers (see [Figure 3.18](#)) embedded in other complex polysaccharides and proteins. The plant cell wall has three major roles:

Figure 5.21 The Plant Cell Wall The semirigid cell wall provides support for plant cells. It is composed of cellulose fibrils embedded in a matrix of polysaccharides and proteins.

- It provides support for the cell and plant by remaining rigid. Yet it is flexible enough that it can allow the plant to bend in the wind, for example.
- It acts as a barrier to infection by fungi and other organisms that can cause plant diseases.
- It contributes to plant form by growing as the plant cells expand.

In some cells, such as those in a leaf, the cell wall is porous to allow the passage of molecules into and out of the cell. In other cells, such as those of the plant's vascular system (which transports water and small molecules between organs), the wall is not porous.

Because of their thick cell walls, plant cells viewed under a light microscope appear to be entirely isolated from one another. But electron microscopy reveals that this is not the case. The cytoplasms of adjacent plant cells are connected by numerous cell membranelined channels called **plasmodesmata**, which are about 20–40 nm in diameter and extend through the cell walls (see [Figure 5.7](#)). Plasmodesmata permit the diffusion of water, ions, small molecules, RNA, and proteins between connected cells, allowing for the use of these substances far from their sites of synthesis. Plasmodesmata also enable communication between adjacent cells.

plasmodesmata (singular: plasmodesma) [Gk. *plassein*: to mold + *desmos*: band]
Cytoplasmic strands connecting two adjacent plant cells.

The extracellular matrix supports tissue functions in animals

Animal cells lack the semirigid wall that is characteristic of plant cells, but many animal cells are surrounded by, or in contact with, an **extracellular matrix**. This matrix is composed of three types of molecules: fibrous proteins such as **collagen** (the most abundant protein in mammals, constituting over 25 percent of the protein in the human body); a matrix of glycoproteins termed **proteoglycans**, consisting primarily of sugars; and a third group of proteins that link the fibrous proteins and the gel-like proteoglycan matrix together (**Figure 5.22**). These proteins and proteoglycans are secreted, along with other substances that are specific to certain body tissues, by cells that are present in or near the matrix.

extracellular matrix A material of heterogeneous composition surrounding cells and performing many functions including adhesion of cells.

collagen [Gk. *kolla*: glue] A fibrous protein found extensively in bone and connective tissue.

proteoglycan A glycoprotein containing a protein core with attached long, linear carbohydrate chains.

Figure 5.22 An Extracellular Matrix Cells in the kidney secrete a basal lamina, which is an extracellular matrix that separates the kidney cells from a nearby blood vessel. The basal lamina filters materials that pass between the kidney and the blood.

The functions of the extracellular matrix are many:

It holds cells together in tissues. In [Chapter 6](#) we will see how there is an intercellular “glue” that is involved in both cell recognition and adhesion.

It contributes to the physical properties of cartilage, skin, and other tissues. For example, the mineral component of bone is laid down on an organized extracellular matrix.

It helps filter materials passing between different tissues. This is especially important in the kidney.

It helps orient cell movements during embryonic development and during tissue repair.

It plays a role in chemical signaling from one cell to another. Proteins connect the cell's cell membrane to the extracellular matrix. These proteins (for example, integrin) span the cell

membrane and are involved with transmitting signals to the interior of the cell. This allows communication between the extracellular matrix and the cytoplasm of the cell.

5.4 recap

Extracellular structures are produced by cells and secreted outside the cell membrane. Most consist of a fibrous component in a gel-like medium.

learning outcomes

You should be able to:

- Explain structure-function relationships in cell walls.
- Compare and contrast plant and animal cell extracellular matrices.
- Analyze changes to cells involving extracellular components.

1. When a cancer spreads from the initial site to another location in the body, initial events are the detachment of the cancer cells from its surrounding extra cellular matrix and digestion of the matrix as the cell migrates. How might these events occur?
2. How does the structure of a cell wall contribute to its function?
3. How could a biologist use chemical analysis to differentiate between a plant cell and an animal cell?

We have now discussed the structures and some functions of prokaryotic and eukaryotic cells. Both exemplify the cell theory, showing that cells are the basic units of life and of biological continuity. Much of the rest of this part of the book will deal with these two aspects of cells. There is abundant evidence that the simpler prokaryotic cells are more ancient than eukaryotic cells, and that the first cells were probably prokaryotic. We will now turn to the next step in cellular evolution, the origin of eukaryotic cells.

5.5 Eukaryotic Cells Evolved in Several Steps

Life on Earth was entirely prokaryotic for about 2 billion years—from the time when prokaryotic cells first appeared until about 1.5 billion years ago, when evidence of eukaryotic cells appears in ancient rocks. The advent of compartmentalization—the hallmark of eukaryotes—was a major event in the history of life. It permitted many more biochemical functions to exist in the same cell than had previously been possible. Compared with a typical eukaryote, a single prokaryotic cell is often biochemically specialized, limited in the resources it can use and the functions it can perform.

focus your learning

Biologists theorize that the endomembrane system and the cell nucleus originated as the result of infoldings of the cell membrane.

The theory of endosymbiosis proposes that organelles arose when cells engulfed other cells, and this arrangement led to symbiotic relationships.

What is the origin of compartmentalization? We will describe the evolution of eukaryotic organelles in more detail in [Key Concept 25.2](#). Here we outline two major themes in this process.

Internal membranes and the nuclear envelope probably came from the cell membrane

We noted earlier in this chapter that some bacteria contain internal membranes. How could these arise? In electron micrographs, the internal membranes of prokaryotes often appear to be inward folds of the cell membrane. This observation has led to a theory that the endomembrane system and the cell nucleus originated by related processes ([Figure 5.23A](#)). The close relationship between the endoplasmic reticulum (ER) and the nuclear envelope in today's eukaryotes is consistent with this theory.

(A) Hypothetical evolution of the ER

(B) Evolution of the chloroplast according to the Theory of Endosymbiosis

Figure 5.23 The Origins of Organelles (A) The endomembrane system and nuclear envelope may have been formed by infolding and then fusion of the cell membrane.

(B) The endosymbiosis theory proposes that some organelles may be descended from prokaryotes that were engulfed by other, larger cells.

A bacterium with enclosed compartments would have several evolutionary advantages. Chemicals could be concentrated in particular regions of the cell, allowing chemical reactions to proceed more efficiently. A biochemical process could be segregated within an organelle with, for example, a different pH from the rest of the cell, creating more favorable conditions for that process. Finally, gene transcription could be separated from translation, providing more opportunities for separate control of these steps in gene expression.

Some organelles arose by endosymbiosis

Symbiosis means “living together,” and often refers to two organisms that coexist, each one supplying something that the other needs. With the **theory of endosymbiosis** biologists have proposed that some organelles—the mitochondria and the plastids—arose not by an infolding of the cell membrane but by one cell ingesting (but not digesting) another cell, giving rise to a symbiotic relationship. Eventually, the ingested cell lost its autonomy and some of its functions. In addition, many of the ingested cell’s genes were transferred to the host’s DNA. Mitochondria

and plastids in today's eukaryotic cells are the remnants of these symbionts, retaining some specialized functions that benefit their host cells.

symbiosis (sim' bee oh' sis) [Gk. *sym*: together + *bios*: living] The living together of two or more species in a prolonged and intimate relationship.

Consider the case of the plastid. About 2.5 billion years ago some prokaryotes (the cyanobacteria) developed photosynthesis. The emergence of these prokaryotes was a key event in the evolution of complex organisms because they increased the O₂ concentration in Earth's atmosphere (see [Key Concept 25.2](#)).

According to the endosymbiosis theory, photosynthetic prokaryotes also provided the precursor of the modern-day plastid. Cells without cell walls can engulf relatively large particles by phagocytosis (see [Figure 5.10](#)). In some cases, such as that of phagocytes in the human immune system, the engulfed particle can be an entire cell, such as a bacterium. Plastids may have arisen by a similar event involving an ancestral eukaryote and a cyanobacterium ([Figure 5.23B](#)).

5.5 recap

Eukaryotic cells arose long after prokaryotic cells. Some organelles may have evolved by infolding of the cell membrane, whereas others probably evolved by endosymbiosis.

learning outcomes

You should be able to:

- Explain how the cell membrane could have been involved in the evolution of the endomembrane system in eukaryotes.
- Relate endosymbiotic theory to observations of modern cells.

1. How could membrane infolding in a prokaryotic cell lead to the formation of the endomembrane system?
2. When they are removed from a cell, organelles such as mitochondria no longer function as they did inside the cell. What aspect of endosymbiotic theory explains this observation?

In this chapter we presented an overview of the components of cells, with some ideas about their structures, functions, and origins. As you now embark on the study of major cellular processes, keep in mind that cellular components do not exist in isolation: they are part of a dynamic, interacting system. In [Chapter 6](#) you will see that the cell membrane is far from a passive barrier, but instead is a multifunctional system that connects the inside of the cell with its extracellular environment.

 investigatinglife

Are pigments compartmentalized in all types of cells?

In this chapter, you learned of several situations in which pigments are concentrated in discrete

organelles: in humans, melanin is packaged in melanosomes in human skin cells; in plants, tannins are packaged in tannosomes, chlorophyll is packaged in thylakoids, other pigments are contained in chromoplasts, and anthocyanins that may attract pollinators and seed dispersers are packaged in the vacuoles in petals and fruits. You learned, too, of the remarkable ability of motor proteins to move pigment granules into the center of cells in fish and amphibians, to lighten their skin color as a defensive mechanism.

Many biological traits and adaptations are linked to pigments in organelles. For example, the distribution of melanosomes is related to eye color, genetically determined errors in the formation of melanosomes can lead to albinism, and a lack of protection against ultraviolet light. In plants, the formation of tannosomes is associated with plant defenses (see [Chapter 38](#)). Understanding the pathway by which tannosomes are formed could have beneficial applications in agriculture. For example, tannins are important to the taste of red wine and manipulating tannin concentrations can result in new flavors.

Future directions

The most common form of human cancer is skin cancer. Most skin cancers are easily treated, but a rare type, melanoma, can be lethal. As its name implies, melanoma occurs when melanocytes in the skin multiply excessively. This can happen if melanocytes are exposed to ultraviolet light from the sun in excess of the ability of their melanin pigment to absorb it. As the tumor develops, it often becomes resistant to the drugs used to treat it. Recent research indicates that one way that drug resistance develops is that the drugs get sucked up by melanosomes and stay in the compartments, preventing them from getting to their targets elsewhere in the cell. Biologists are trying to develop drugs that target melanosomes to prevent this drug sequestration.

5.1 Cells Are the Fundamental Units of Life

- The [cell theory](#) is the unifying theory of cell biology. All living things are composed of cells, and all cells come from preexisting cells.

cell theory States that cells are the basic structural and physiological units of all living organisms, and that all cells come from preexisting cells.

- A cell is small and maintains a large [surface area-to-volume ratio](#). This allows it to exchange adequate quantities of materials with its environment. !![Review Figures 5.1, 5.2, Activity 5.1](#)

surface area-to-volume ratio For any cell, organism, or geometrical solid, the ratio of surface area to volume; this is an important factor in setting an upper limit on the size a cell or organism can attain.

- Cell structures can be studied with light and electron microscopes. !![Review Figure 5.3, Activity 5.2](#)
- All cells are enclosed by a selectively permeable [cell membrane](#) that separates their contents from the external environment.

cell membrane The membrane that surrounds the cell, regulating the entry and exit of molecules and ions. Every cell has a cell membrane, and it is also called the plasma membrane.

- Whereas certain biochemical processes, molecules, and structures are shared by all kinds of cells, there are two categories of organisms—**prokaryotes** and [eukaryotes](#)—that can be distinguished by characteristic cell structures.

eukaryotes (yew car' ree oats) [Gk. *eu*: true + *karyon*: kernel or nucleus] Organisms whose cells contain their genetic material inside a nucleus. Includes all life other than the viruses, prokaryotic archaea, and bacteria. (Contrast with prokaryotes.)

- Eukaryotic cells are generally larger and more complex than prokaryotic cells. They contain membrane-bound [organelles](#), including the nucleus.

organelle (or gan el') Any of the membrane-enclosed structures within a eukaryotic cell. Examples include the nucleus, endoplasmic reticulum, and mitochondria.

5.2 Prokaryotic Cells Are the Simplest Cells

- prokaryotic cells have no internal compartments but have a [nucleoid](#) region containing DNA. The rest of the material inside the cell membrane, including the [ribosomes](#), is

called the **cytoplasm** (or cytosol). Some prokaryotes have additional protective structures, including a **cell wall**, an **outer membrane**, and a **capsule**. **Review Figure 5.4**

nucleoid (new' klee oid) The region that harbors the chromosomes of a prokaryotic cell. Unlike the eukaryotic nucleus, it is not bounded by a membrane.

ribosome A small particle in the cell that is the site of protein synthesis.

cytoplasm The contents of the cell, excluding the nucleus.

cell wall A relatively rigid structure that encloses cells of plants, fungi, many protists, and most prokaryotes, and which gives these cells their shape and limits their expansion in hypotonic media.

capsule In some prokaryotes, a dense layer of polymers that surrounds the cell wall.

- Some prokaryotes have folded **internal membranes** such as those used in photosynthesis, and some have **flagella** or **pili** for motility or attachment. **Review Figure 5.5**
- filamentous proteins in the cytoplasm make up the **cytoskeleton**, which assists in cell division and the maintenance of cell shape.

cytoskeleton The network of microtubules and microfilaments that gives a eukaryotic cell its shape and its capacity to arrange its organelles and to move.

5.3 Eukaryotic Cells Contain Organelles

See **Activity 5.3**

- Eukaryotic cells are larger than prokaryotic cells and contain many membrane-enclosed **organelles**. The membranes that envelop organelles ensure compartmentalization of their functions. **Review Figure 5.7**

organelle (or gan el') Any of the membrane-enclosed structures within a eukaryotic cell. Examples include the nucleus, endoplasmic reticulum, and mitochondria.

- The **nucleus** contains most of the cell's DNA and participates in the control of protein synthesis. The DNA and the proteins associated with it form a material called **chromatin**. Each long, thin DNA molecule occurs in a discrete chromatin structure called a **chromosome**. **Review Figure 5.8**

nucleus (new' klee us) [L. *nux*: kernel or nut] (1) In cells, the centrally located compartment of eukaryotic cells that is bounded by a double membrane and contains the chromosomes. (2) In the brain, an identifiable group of neurons that share common characteristics or functions.

chromatin The nucleic acid–protein complex that makes up eukaryotic chromosomes.

chromosome (krome' o sowm) [Gk. *kroma*: color + *soma*: body] In bacteria and viruses, the DNA molecule that contains most or all of the genetic information of the cell or virus. In eukaryotes, a structure composed of DNA and proteins that bears part of the genetic information of the cell.

- Within the nucleus is the **nucleolus**, where ribosome assembly begins. The **ribosomes**

function as sites of protein synthesis.

nucleolus (new klee' oh lus) A small, generally spherical body found within the nucleus of eukaryotic cells. The site of synthesis of ribosomal RNA.

ribosome A small particle in the cell that is the site of protein synthesis.

- The **endomembrane system**—consisting of the cell membrane, the nuclear envelope, the **endoplasmic reticulum**, the **Golgi apparatus**, and **lysosomes**—is a series of interrelated compartments enclosed by membranes. It segregates proteins and modifies them. **Lysosomes** contain many digestive enzymes. !!**Review Focus: Key Figure 5.9, Figure 5.10, Activity 5.4, Animation 5.1**

endomembrane system A system of intracellular membranes that exchange material with one another, consisting of the Golgi apparatus, endoplasmic reticulum, and lysosomes when present.

endoplasmic reticulum (ER) [Gk. *endo*: within + L. *reticulum*: net] A system of membranous tubes and flattened sacs found in the cytoplasm of eukaryotes. Exists in two forms: rough ER, studded with ribosomes; and smooth ER, lacking ribosomes.

Golgi apparatus (goal' jee) A system of concentrically folded membranes found in the cytoplasm of eukaryotic cells; functions in secretion from the cell by exocytosis.

lysosome (lie' so soam) [Gk. *lysis*: break away + *soma*: body] A membrane-enclosed organelle originating from the Golgi apparatus and containing hydrolytic enzymes. (Contrast with secondary lysosome.)

lysosome (lie' so soam) [Gk. *lysis*: break away + *soma*: body] A membrane-enclosed organelle originating from the Golgi apparatus and containing hydrolytic enzymes. (Contrast with secondary lysosome.)

- **Mitochondria** and **chloroplasts** are organelles that process energy. Mitochondria are present in all eukaryotic organisms and contain the enzymes needed for **cellular respiration**. The cells of photosynthetic eukaryotes contain chloroplasts that harvest light energy for photosynthesis. !!**Review Figures 5.11, 5.12**

mitochondria (my' toe kon' dree uh) (singular: mitochondrion) [Gk. *mitos*: thread + *chondros*: grain] Energy-generating organelles in eukaryotic cells that contain the enzymes of the citric acid cycle, the respiratory chain, and oxidative phosphorylation.

chloroplast [Gk. *chloros*: green + *plast*: a particle] An organelle bounded by a double membrane containing the enzymes and pigments that perform photosynthesis. Chloroplasts occur only in eukaryotes.

cellular respiration The catabolic pathways by which electrons are removed from various molecules and passed through intermediate electron carriers to O₂, generating H₂O and releasing energy.

- Large **vacuoles** are present in many plant cells. A vacuole consists of a membrane-enclosed compartment full of water and dissolved substances.

vacuole (vac' yew ole) Membrane-enclosed organelle in plant cells that can function for storage, water concentration for turgor, or hydrolysis of stored macromolecules.

- The [microfilaments](#), [intermediate filaments](#), and [microtubules](#) of the cytoskeleton provide the cell with shape, strength, and movement. !![Review Figures 5.14, 5.15, 5.16](#)

microfilament In eukaryotic cells, a fibrous structure made up of actin monomers.

Microfilaments play roles in the cytoskeleton, in cell movement, and in muscle contraction.

intermediate filaments A part of the cytoskeleton that includes filaments intermediate in diameter between microtubules and microfilaments.

microtubules Tubular structures found in centrioles, spindle apparatus, cilia, flagella, and cytoskeleton of eukaryotic cells. These tubules play roles in the motion and maintenance of shape of eukaryotic cells.

- [Motor proteins](#) use cellular energy to change shape and move. They drive the bending movements of cilia and flagella, and transport organelles along microtubules within the cell. !![Review Figures 5.18, 5.19](#)

motor proteins Specialized proteins that use energy to change shape and move cells or structures within cells.

5.4 Extracellular Structures Have Important Roles

- The plant cell wall consists principally of cellulose. Cell walls are pierced by [plasmodesmata](#) that join the cytoplasm of adjacent cells.

plasmodesmata (singular: plasmodesma) [Gk. *plassein*: to mold + *desmos*: band] Cytoplasmic strands connecting two adjacent plant cells.

- In animal cells, the [extracellular matrix](#) consists of different kinds of proteins, including [collagen](#) and [proteoglycans](#). [Review Figure 5.22](#)

extracellular matrix A material of heterogeneous composition surrounding cells and performing many functions including adhesion of cells.

collagen [Gk. *kolla*: glue] A fibrous protein found extensively in bone and connective tissue.

proteoglycan A glycoprotein containing a protein core with attached long, linear carbohydrate chains.

5.5 Eukaryotic Cells Evolved in Several Steps

- Infoldings of the cell membrane could have led to the formation of some membrane-enclosed organelles, such as the endomembrane system and the nucleus. [Review Figure 5.23A](#)
- [Symbiosis](#) means “living together.” The **theory of endosymbiosis** states that mitochondria and chloroplasts originated when larger cells engulfed, but did not digest, smaller cells. Mutual benefits permitted this symbiotic relationship to be maintained, allowing the smaller cells to evolve into the eukaryotic organelles observed today. [Review Figure 5.23B](#)

symbiosis (sim' bee oh' sis) [Gk. *sym*: together + *bios*: living] The living together of two or more species in a prolonged and intimate relationship.

Review

- .1 Membranes provide a structural role in a cell and also allow the cell to maintain homeostasis and communicate with other cells.
- .1 Microscopy allows visual examination of cells.
- .3 Each organelle carries out a different specific function that, when combined with others, allows the cell to function as a whole.

Original Paper: Hirschberg, K. et al. 1998. Kinetic analysis of secretory protein traffic and characterization of Golgi to plasma membrane transport intermediates in living cells. *The Journal of Cell Biology* 143: 1485–1503.

Some proteins naturally emit light. One example is green fluorescent protein found in the jellyfish *Aequorea victoria*, which emits a green glow from the rim of its circular body. Scientists are not sure what biological role green fluorescent protein plays in the jellyfish, though one hypothesis is that the light scares off predators. While research on this question is ongoing, green fluorescent protein has been put to work as a useful biological tool. The gene encoding the protein has been isolated and small portions of it linked to genes encoding proteins from other organisms. Expression of these fused genes produces “fusion proteins” that retain their normal biological functions but have fluorescent tags that allow the proteins to be tracked.

Researchers followed such a fusion protein through a mammalian cell using microscopy. They fused genetic sequences from green fluorescent protein to the gene encoding a protein from a virus. When this virus infects a cell, it directs the cell to make this protein and insert it into the cell membrane. The membrane is used to package new viruses. By choosing this protein, the researchers identified a nice system for following a protein's movements through a cell. They used a microscope outfitted with fluorescence imaging equipment to observe changes after infecting the cell with virus. The table below summarizes the results.

Time (min)	Relative fluorescence intensity			
	ER	Golgi apparatus	Cell membrane	Total
0	0.95	0.05	0.00	1.00
20	0.64	0.28	0.08	1.00
40	0.38	0.39	0.23	1.00

60	0.17	0.38	0.44	0.99
80	0.05	0.28	0.65	0.98
100	0.00	0.25	0.70	0.95
150	0.00	0.05	0.77	0.82
200	0.00	0.00	0.75	0.75

Questions

1. Create a graph plotting the fluorescence intensity versus time for each category. Use the results to describe the pathway taken by the protein.
2. Suppose that the mammalian cells had been given a molecule that inhibited protein synthesis at the same time they were inoculated with the virus carrying the gene for the fusion protein. How would this have affected the results of the experiment?
3. Another way to track the tagged protein is cell fractionation. If cells are infected with the virus and at various times ruptured and cell fractions isolated by centrifugation, the fluorescent protein can be identified in specific fractions at each time point. Would the researchers have learned anything different using this method? Explain.
1. Green fluorescent protein is not the only fluorescent protein that biologists have used as a tag for following proteins. How do you think researchers could use fluorescent tagging to follow two different proteins simultaneously in the same cell? Could the researchers use this to show how two proteins end up in different locations?
2. Create a graph or table to predict the results of an experiment in which researchers follow the fates of two proteins after they are made on ribosomes in the rough ER: a secretory protein destined to be secreted by the cell and a peroxidase destined for the peroxisome.

Sweating and Membranes

During World War II, Winston Churchill told the British Parliament, “I have nothing to offer but blood, toil, tears and sweat.” He may not have known that the last two, tears and sweat, are transported across cell membranes inside vesicles. As you saw in [Chapter 2](#), sweating is a way to reduce body heat by using excess heat to evaporate water. At peak activity, we may lose as much as 2 liters of water an hour, and if you know about the German air attacks on London during the war, you know that the people indeed toiled hard and must have sweated a lot.

The sweat glands lie just below the surface of the skin. They are essentially cell-lined tubes surrounded by extracellular fluid. When sweating is triggered, these tubes fill with water and dissolved substances. To get from the extracellular fluid into the tube, water must go through the cells that line the tube.

A hallmark of living cells is the ability to regulate what enters and leaves the cytoplasm. This is a function of the cell membrane, a hydrophobic lipid bilayer with associated proteins. Because it is insoluble in the aqueous environment both inside and outside cells, the membrane is a physical barrier. But it is also a functional barrier. Whereas water is polar, the interior of the membrane is nonpolar—so water has a natural tendency to avoid the membrane. The rate of movement of water across a lipid bilayer is modest. When you engage in normal activities such as reading this book, the cell membranes enclosing the cells lining the sweat glands do not allow much water to enter or leave. But when you exercise vigorously, tiny membrane-enclosed vesicles inside the cells fill with water and some dissolved salts. In a process called exocytosis, these vesicles fuse with the cell membrane and release their watery contents (sweat) into the tubes. From there the sweat flows to the surface of the skin and evaporates.

Vesicles are not the only way to get polar water across a nonpolar membrane. In the mammalian kidney, and in plant roots, stems, and leaves, special pores called aquaporins occur in the cell membrane. Water can flow through them readily because the proteins lining the channel have a hydrophilic inner surface.

What is the importance of aquaporin membrane channels?

6.1 Biological Membranes Are Lipid–Protein Bilayers

The physical organization and functioning of all biological membranes depend on their constituents: lipids, proteins, and carbohydrates. You are already familiar with these molecules from [Chapter 3](#) and with membranes that enclose cells and organelles from [Chapter 5](#). Lipids establish the physical integrity of the membrane and create a barrier to the rapid passage of hydrophilic materials such as water and ions. In addition, the phospholipid bilayer serves as a lipid “lake” in which a variety of proteins “float” (**Focus: Key Figure 6.1**). This general design is known as the **fluid mosaic model**. It is *mosaic* because it is made up of many discrete components, and *fluid* because the components can move freely.

focus: key figure

Figure 6.1 The Fluid Mosaic Model The general molecular structure of a biological membrane is a continuous phospholipid bilayer that has proteins embedded in it or associated with it.

Activity 6.1 The Fluid Mosaic Model www.Life11e.com/ac6.1

Q: What kinds of chemical interactions hold some membrane proteins embedded in the membrane and others on the membrane surface?

of a fluid phospholipid bilayer in which suspended proteins are free to move in the plane of the bilayer.

focus your learning

A lipid bilayer forms as the result of two kinds of interactions: hydrophobic interactions between nonpolar tails of phospholipids, and hydrophilic interactions between polar heads of phospholipids and water molecules.

Proteins associated with membranes may be embedded in the lipid bilayer or associated with exposed parts of the membrane.

Membranes are dynamic structures that undergo constant change.

The degree of a membrane's fluidity is influenced by lipid composition and temperature.

The fluid mosaic model depicts proteins as noncovalently embedded in the phospholipid bilayer by their hydrophobic regions (or domains) or tethered to lipids inserted into the membrane. Proteins may span the membrane or may be bound on the surface. Their hydrophilic regions are exposed to the watery conditions on either side of the bilayer. Membrane proteins have several functions, including moving materials through the membrane and receiving chemical signals from the cell's external environment. Each membrane has a set of proteins suitable for the specialized functions of the cell or organelle it surrounds.

The carbohydrates associated with membranes are attached either to the lipids or to protein molecules. In cell membranes, carbohydrates are located on the outside of the cell, where they may interact with substances in the external environment. Like some of the membrane proteins, carbohydrates are crucial in recognizing specific molecules, such as those on the surfaces of adjacent cells.

Although the fluid mosaic model is largely valid for membrane structure, it does not say much about membrane composition. As you read about the various molecules in membranes in the next sections, keep in mind that some membranes have more protein than lipids, others are lipid-rich, others have significant amounts of cholesterol or other sterols, and still others are rich in carbohydrates.

Lipids form the hydrophobic core of the membrane

The lipids in biological membranes are usually ***phospholipids**. Recall from [Key Concept 2.2](#) that some compounds are hydrophilic ("water-loving") and others are hydrophobic ("water-hating"), and from [Key Concept 3.4](#) that a phospholipid molecule has regions of both kinds:

- . *Hydrophilic regions:* The phosphate-containing "head" of the phospholipid is electrically charged and therefore associates with polar water molecules.
- . *Hydrophobic regions:* The long, nonpolar fatty acid "tails" of the phospholipid associate with other nonpolar materials; they do not dissolve in water or associate with hydrophilic substances.

The chemical properties of phospholipids are such that when phospholipids coexist with water, they form a bilayer, with the fatty acid "tails" of the two layers interacting with each other and the polar "heads" facing the outside aqueous environment ([Figure 6.2](#)). The thickness of a biological membrane is about 8 nanometers (0.008 μm), which is twice the length of a typical phospholipid—another indication that the membrane consists of a lipid bilayer. To give you an idea of the scale, a typical sheet of paper is about 8,000 times thicker than this.

Figure 6.2 Phospholipid Bilayer The phospholipid bilayer separates two aqueous regions. The eight phospholipid molecules shown on the right represent a small cross section of a membrane bilayer.

All biological membranes have a similar structure, but they differ in the kinds of proteins and lipids they contain. Membranes from different cells or organelles may differ greatly in their lipid composition. Phospholipids can differ in terms of fatty acid chain length (number of carbon atoms), degree of unsaturation (number of double bonds) in the fatty acids, and the polar groups present (see [Chapter 3](#)). The saturated chains allow close packing of fatty acids in the bilayer, whereas the “kinks” in unsaturated fatty acids (see [Figure 3.21](#)) make for a less dense, more fluid packing.

Up to 25 percent of the lipid content of an animal cell’s cell membrane may be the steroid cholesterol (see [Key Concept 3.4](#)). Cholesterol preferentially associates with saturated fatty acids. When present, cholesterol is important for membrane integrity; the cholesterol in your membranes is not hazardous to your health.

The fatty acids of the phospholipids make the hydrophobic interior of the membrane somewhat fluid—about as fluid as lightweight olive oil. This fluidity permits some molecules to move laterally within the plane of the membrane.

A given phospholipid molecule in the cell membrane can travel from one end of the cell to the other in a little more than a second! However, a phospholipid molecule in one half of the bilayer is unlikely to spontaneously flip over to the other side. For that to happen, the polar part of the molecule would have to move through the hydrophobic interior of the membrane. Since spontaneous phospholipid flip-flops are rare, the inner and outer halves of the bilayer may be quite different in the kinds of phospholipids they contain.

Membrane fluidity is affected by several factors, two of which are particularly important:

Lipid composition: Cholesterol and long-chain, saturated fatty acids pack tightly beside one another, with little room for movement. This close packing results in less-fluid membranes. A membrane with shorter-chain fatty acids, unsaturated fatty acids, or less cholesterol is more fluid.

Temperature: Because molecules move more slowly and fluidity decreases at reduced temperatures, cellular processes that take place within the membrane may slow down or stop under cold conditions in organisms that cannot keep their bodies warm. To address this problem, in some organisms the lipid composition of their membranes changes when they get cold, replacing saturated with unsaturated fatty acids and using fatty acids with shorter tails. These changes play a role in the survival of plants, bacteria, and hibernating animals during the winter.

 Activity 6.2 **Lipid Bilayer Composition Simulation** www.Life11e.com/ac6.2

Membrane proteins are asymmetrically distributed

All biological membranes contain proteins. Typically, cell membranes have 1 protein molecule for every 25 lipid molecules. This ratio varies depending on membrane function. In the inner membrane of the mitochondrion, which is specialized for energy processing, there is 1 protein for every 15 lipids. However, myelin—a modified cell membrane that encloses portions of some neurons (nerve cells) and acts as an electrical insulator—has only 1 protein for every 70 lipids.

Membrane proteins are very diverse. In fact, about one-fourth of the protein-coding genes in the eukaryotic genome encode membrane proteins. There are two general types of membrane proteins: integral proteins and peripheral proteins.

Integral membrane proteins are at least partly embedded in the phospholipid bilayer (see [Figure 6.1](#)). Like phospholipids, these proteins have both hydrophilic and hydrophobic regions (domains) ([Figure 6.3](#)).

integral membrane proteins Proteins that are at least partially embedded in the plasma membrane. (Contrast with peripheral membrane proteins.)

Figure 6.3 Interactions of Integral Membrane Proteins An integral membrane protein is held in the membrane by the distribution of the hydrophilic and hydrophobic side chains on its amino acids. The hydrophilic parts of the protein extend into the aqueous cell exterior and the internal cytoplasm. The hydrophobic side chains interact with the hydrophobic lipid core of the membrane.

- *Hydrophilic domains:* Stretches of amino acids with hydrophilic side chains (R groups; see [Table 3.2](#)) give certain regions of the protein a polar character. These hydrophilic domains interact with water and stick out into the aqueous environment inside or outside the cell.
- *Hydrophobic domains:* Stretches of amino acids with hydrophobic side chains give other regions of the protein a nonpolar character. These domains interact with the fatty acids in the interior of the phospholipid bilayer, away from water. Some proteins contain covalently linked lipids such as fatty acid chains that do the job of inserting into the membrane (instead of the protein having hydrophobic amino acid regions).

Peripheral membrane proteins lack exposed hydrophobic groups and are not embedded in the bilayer. Instead, they have polar or charged regions that interact with exposed parts of integral membrane proteins, or with the polar heads of phospholipid molecules (see [Figure 6.1](#)).

A special preparation method for electron microscopy, called freeze-fracturing, reveals proteins that are embedded in the phospholipid bilayers of cellular membranes ([Figure 6.4](#)). When the two lipid leaflets (or layers) that make up the bilayer are separated, the proteins can be seen as bumps that protrude from the interior of each membrane. The bumps are not observed when artificial bilayers of pure lipid are freeze-fractured.

Figure 6.4 Membrane Proteins Revealed by the Freeze-Fracture Technique This HeLa cell (a human cell) membrane was first frozen to immobilize the lipids and proteins, and then fractured so that the bilayer was split open.

Membrane proteins and lipids generally interact only noncovalently. The polar ends of proteins can interact with the polar ends of lipids, and the nonpolar regions of both molecules can interact hydrophobically. As mentioned above, however, some membrane proteins have hydrophobic lipid components covalently attached to them that allow these proteins to tether themselves to the phospholipid bilayer.

Proteins are asymmetrically distributed on the inner and outer surfaces of membranes. An integral protein that extends all the way through the phospholipid bilayer and protrudes on both sides is known as a **transmembrane protein**. In addition to one or more **transmembrane domains** that extend through the bilayer, such a protein may have domains with other specific functions on the inner and outer sides of the membrane. Peripheral membrane proteins, by contrast, are located on one side of the membrane or the other. This asymmetrical arrangement of membrane proteins gives the two surfaces of the membrane different properties. As you will soon see, these differences have great functional significance.

transmembrane protein An integral membrane protein that spans the phospholipid bilayer.

transmembrane domain A protein region rich in hydrophobic amino acids that spans the phospholipid bilayer.

Like lipids, some membrane proteins move around relatively freely within the phospholipid bilayer. Experiments that involve the technique of cell fusion illustrate this migration dramatically. When two cells are fused, a single continuous membrane forms and surrounds both cells, and some proteins from each cell distribute themselves uniformly around this membrane (**Figure 6.5**).

Figure 6.5 Rapid Diffusion of Membrane Proteins

Original Paper: Frye, L. D. and M. Edidin. 1970. The rapid intermixing of cell surface antigens after formation of mouse-human heterokaryons. *Journal of Cell Science* 7: 319–335.

Two animal cells can be fused together in the laboratory, forming a single large cell (heterokaryon). This phenomenon was used to test whether membrane proteins can diffuse independently in the plane of the cell membrane.

HYPOTHESIS ▶ Proteins embedded in a membrane can diffuse freely within the membrane.

METHOD

The mouse cell has a membrane protein that can be labeled with a green dye.

The human cell has a membrane protein that can be labeled with a red dye.

RESULTS

1 The cells are fused together to create a heterokaryon.

2 Initially, the mouse and human membrane proteins are on different sides of the heterokaryon.

3 After 40 minutes, the mouse and human membrane proteins are intermixed.

CONCLUSION ▶ Membrane proteins can diffuse rapidly in the plane of the membrane.

Although some proteins are free to migrate in the membrane, others are not, but rather appear to be “anchored” to a specific region of the membrane. These membrane regions are like an enclosure of animals at the zoo: the animals are free to move around within the fenced area but not outside it. An example is the protein in the cell membrane of a muscle cell that recognizes a chemical signal from a neuron. This protein is normally found only at the specific region where the neuron meets the muscle cell. Proteins inside the cell can restrict the movement of proteins within a membrane. The cytoskeleton has components just below the inner face of the membrane that are attached to membrane proteins protruding into the cytoplasm. The stability of the cytoskeletal components may thus restrict movement of attached membrane proteins.

Membranes are constantly changing

Membranes in eukaryotic cells are constantly forming, transforming from one type to another, fusing with one another, and breaking down. As we discussed in [Chapter 5](#), fragments of membrane move, in the form of vesicles, from the endoplasmic reticulum (ER) to the Golgi apparatus, and from the Golgi apparatus to the cell membrane (see [Figure 5.9](#)). Secondary lysosomes form when primary lysosomes from the Golgi apparatus fuse with phagosomes from the cell membrane (see [Figure 5.10](#)).

Because all membranes appear similar under the electron microscope, and because they interconvert readily, we might expect all subcellular membranes to be chemically identical. However, that is not the case: there are major chemical differences among the membranes of even a single eukaryotic cell. Membranes are changed chemically when they form parts of certain organelles. In the Golgi apparatus, for example, the membranes of the *cis* face closely resemble those of the ER in chemical composition, but those of the *trans* face are more similar to the cell membrane.

Cell membrane carbohydrates are recognition sites

In addition to lipids and proteins, the cell membrane contains carbohydrates (see [Figure 6.1](#)). The carbohydrates are located on the outer surface of the cell membrane and serve as recognition sites for other cells and molecules, as you will see in [Key Concept 6.2](#).

Membrane-associated carbohydrates may be covalently bonded to lipids or to proteins:

A **glycolipid** consists of a carbohydrate covalently bonded to a lipid. Extending out from the cell surface, the carbohydrate may serve as a recognition signal for interactions between cells. For example, the carbohydrates on some glycolipids change when cells become cancerous. This change may allow white blood cells to target cancer cells for destruction.

A **glycoprotein** consists of one or more short carbohydrate chains covalently bonded to a protein. The bound carbohydrates are oligosaccharides, usually not exceeding 15 monosaccharide units in length (see [Key Concept 3.3](#)). A proteoglycan (see [Key Concept 5.4](#)) is a more heavily glycosylated protein: it has more carbohydrate molecules attached to it, and the carbohydrate chains are often longer than they are in glycoproteins. The carbohydrates of glycoproteins and proteoglycans often function in cell recognition and adhesion.

glycolipid A lipid to which sugars are attached.

glycoprotein A protein to which sugars are attached.

The “alphabet” of monosaccharides on the outer surfaces of membranes can generate a large diversity of messages. Recall from [Key Concept 3.3](#) that monosaccharides are simple carbohydrates, often containing five or six carbons in a ring structure, which can bond with one

another in various configurations. They may form linear or branched oligosaccharides with many different three-dimensional shapes. An oligosaccharide of a specific shape on one cell can bind to a complementary shape on an adjacent cell. This binding is the basis of cell–cell adhesion.

6.1 recap

The fluid mosaic model applies to the cell membrane and the membranes of organelles. In the aqueous environment of the cell, phospholipids spontaneously assemble into a bilayer. The cell membrane is considered fluid because the phospholipids and some of the proteins that compose it can move within their monolayer. An integral membrane protein has both hydrophilic and hydrophobic domains, which affect its position and function in the membrane. Peripheral membrane proteins are bound to one side or the other of the membrane. Carbohydrates that attach to lipids and proteins on the outside of the membrane serve as recognition and adhesion sites for adjacent cells.

learning outcomes

You should be able to:

- Explain how the hydrophobic and hydrophilic regions of phospholipids are involved in membrane formation.
- Differentiate between integral proteins and peripheral proteins.
- Design an experiment to compare the properties of membranes in different types of cells.
- Compare and contrast information provided by freeze-fracturing techniques and cell fusion experiments.

1. How do the hydrophobic and hydrophilic regions of phospholipids form a membrane bilayer?
2. What differentiates an integral protein from a peripheral protein?
3. What information about membranes is derived from freeze-fracturing and cell fusion experiments?
4. When a normal lung cell becomes a lung cancer cell, there are several important changes in cell membrane properties. How would you investigate the observation that the cancer cell membrane is more fluid, with more rapid diffusion in the plane of the membrane of both lipids and proteins?

Now that you understand the structure of biological membranes, let's see how their components function. In the next section we'll focus on the membrane that surrounds individual cells: the cell membrane. We'll then look at how the cell membrane allows individual cells to be grouped together into multicellular systems of tissues.

***connect the concepts** The straight chains of fatty acids allow phospholipids to pack closely together. Review the molecular structure and properties of phospholipids in [Key Concept 3.4](#).

6.2 The Cell Membrane Is Important in Cell Adhesion and Recognition

Often the cells of multicellular organisms exist in specialized groups with similar functions, called tissues. Your body has about 60 trillion cells organized into various kinds of tissues—such as muscle, nerve, and epithelium. Two processes allow cells to arrange themselves in groups:

- [Cell recognition](#), in which one cell specifically recognizes and binds to another cell of a certain type
- [Cell adhesion](#), in which the connection between the two cells is strengthened

cell recognition Binding of cells to one another mediated by membrane proteins or carbohydrates.

cell adhesion The binding of one cell to another, often mediated by noncovalent forces.

Both processes involve the cell membrane. One way to study these processes is to break down a tissue into its individual cells and then allow them to adhere to one another again. This type of experiment is most easily done in relatively simple organisms, such as sponges, which provide good models for studying processes that also occur in the complex tissues of larger species.

focus your learning

Cell adhesion and cell recognition are specific and depend on protein and carbohydrate molecules present on the cell membrane.

After two cells recognize and bind to one another, they can contribute additional material to form stable cell junctions that enhance protective, structural, or communication functions in the organism.

Sponges are multicellular marine animals that have only a few distinct cell layers (see [Key Concept 30.5](#)). The cells of a sponge adhere to one another but can be separated mechanically by passing the animal several times through a fine wire screen ([Figure 6.6](#)). Through this process, what was a single animal becomes hundreds of individual cells suspended in seawater. If such cells are stirred gently for a few hours, cell recognition occurs: the cells bump into and recognize one another, sticking together in the same shape and tissue organization as the original sponge. This recognition is species-specific; if disaggregated sponge cells from two different species are placed in the same container and shaken, individual cells will stick only to other cells of the same species. Two different sponges form, just like the ones at the start of the experiment.

Figure 6.6 Cell Recognition and Adhesion In most cases (including the aggregation of animal cells into tissues), the binding between molecules is homotypic (same to same).

Such tissue-specific and species-specific cell recognition and cell adhesion are essential to the formation and maintenance of tissues in multicellular organisms. Think of your own body. What keeps muscle cells bound to muscle cells and skin to skin? Specific cell adhesion is so obvious a characteristic of complex organisms that it is easy to overlook. You will see many examples of specific cell adhesion throughout this book; here we describe its general principles. As you will see, cell recognition and cell adhesion depend on cell membrane proteins.

Cell recognition and adhesion involve proteins and carbohydrates at the cell surface

The molecules responsible for cell recognition and adhesion in sponges are proteoglycans (often 80% carbohydrate by molecular weight) that carry two kinds of carbohydrates. One kind is relatively small and binds to membrane components, keeping the proteoglycan attached to the cell. The other kind of carbohydrate is a larger, sulfated polysaccharide. If the sulfated polysaccharide from a particular species of sponge is purified and attached to cellulose beads, the beads will aggregate together or with sponge cells—but only with cells of the same species from which the polysaccharide was purified. This demonstrates that the sulfated polysaccharide is responsible for both the specific recognition and adhesion of the sponge cells.

Cell adhesion can result from interactions between the carbohydrates that are parts of glycolipids, glycoproteins, or proteoglycans—as is the case in sponge cells. In other cases, a carbohydrate on one cell interacts with a membrane protein on another cell. Or two proteins can interact directly. As we described in [Key Concept 3.2](#), a protein not only has a specific shape, it also has specific chemical groups exposed on its surface where they can interact with other substances, including other proteins. Both of these features allow binding to other specific molecules. Cell adhesion occurs in all kinds of multicellular organisms. In plants, cell adhesion may be mediated by both integral membrane proteins and specific carbohydrates in the cell walls.

In most cases, the binding of cells in a tissue is [homotypic](#); that is, the same molecule sticks out of both cells, and the exposed surfaces fit together and bind to each other. This is a factor that keeps skin cells together in a sheet of cells. But [heterotypic](#) binding (between different molecules on different cells) also occurs. In this case, chemical groups on different surface molecules have an affinity for one another. For example, when the mammalian sperm meets the egg, different proteins on the two types of cells have complementary binding surfaces. Similarly, some algae form male and female reproductive cells (analogous to sperm and eggs) that have flagella to propel them toward each other. Male and female cells can recognize each other by heterotypic glycoproteins on their flagella.

homotypic Pertaining to adhesion of cells of the same type.

heterotypy [Gk. different kind] Alteration in a developmental regulatory gene itself rather than the expression of the genes it controls. (Contrast with heterochrony, heterometry.)

Three types of cell junctions connect adjacent cells

In a complex multicellular organism, cell recognition molecules allow specific types of cells to bind to one another. Often, after the initial binding, both cells contribute material to form additional membrane structures that connect them to one another. These specialized structures, called [cell junctions](#), are most evident in electron micrographs of epithelial tissues, which are layers of cells that line body cavities or cover body surfaces. These surfaces often receive stresses or must retain their contents under pressure, so it is particularly important that their cells adhere tightly. We will examine three types of cell junctions that enable animal cells to seal intercellular spaces, reinforce attachments to one another, and communicate with each other. Tight junctions, desmosomes, and gap junctions, respectively, perform these three functions ([Figure 6.7](#)).

cell junctions Specialized structures associated with the plasma membranes of epithelial cells. Some contribute to cell adhesion, others to intercellular communication.

Figure 6.7 Junctions Link Animal Cells Together Tight junctions (A) and desmosomes (B) are abundant in epithelial tissues. Gap junctions (C) are also found in some muscle and nerve tissues, in which rapid communication between cells is important. Although all three junction types are shown in the cell at the top left, all three are not necessarily seen at the same time in actual cells.

 Activity 6.3 **Animal Cell Junctions** www.Life11e.com/ac6.3

- **Tight junctions** prevent substances from moving through the spaces between cells. For example, cells lining the bladder have tight junctions so urine cannot leak out into the body cavity. Another important function of tight junctions is to maintain distinct faces of a cell within a tissue by restricting the migration of membrane proteins over the cell surface from one face to the other. This may result in a certain function (e.g., endocytosis) being confined to one region of the cell surface.
- **Desmosomes** hold neighboring cells firmly together, acting like spot welds or rivets. Materials can still move around in the extracellular matrix. This provides mechanical stability for tissues such as skin that receive physical stress.
- **Gap junctions** are channels that run between membrane pores in adjacent cells, allowing substances to pass between cells. In the heart, for example, gap junctions allow the rapid spread of electric current (mediated by ions) so the heart muscle cells beat in unison.

tight junction A junction between epithelial cells in which there is no gap between adjacent cells.

desmosome (dez' mo sowm) [Gk. *desmos*: bond + *soma*: body] An adhering junction between animal cells.

gap junction A 2.7-nanometer gap between cell membranes of two animal cells, spanned by protein channels. Gap junctions allow chemical substances or electrical signals to pass from cell to cell.

Cell membranes adhere to the extracellular matrix

In [Key Concept 5.4](#) you learned about the extracellular matrix of animal cells, which is composed of collagen protein arranged in fibers in a gelatinous matrix of proteoglycans. The attachment of a cell to the extracellular matrix is important in maintaining the integrity of a tissue. In addition, some cells can detach from their neighbors, move, and attach to other cells; this is often mediated by interactions with the extracellular matrix.

A transmembrane protein called **integrin** often mediates the attachment of epithelial cells to the extracellular matrix ([Figure 6.8A](#)). More than 24 different integrins have been described in human cells. All of them bind to a protein in the extracellular matrix outside the cell, and to actin filaments, which are part of the cytoskeleton, inside the cell. So in addition to adhesion, integrin has a role in maintaining cell structure via its interaction with the cytoskeleton.

integrin In animals, a transmembrane protein that mediates the attachment of epithelial cells to the extracellular matrix.

Figure 6.8 Integrins and the Extracellular Matrix (A) Integrins mediate the attachment of cells to the extracellular matrix. **(B)** Cell movements are mediated by integrin attachment.

The binding of integrin to the extracellular matrix is noncovalent and reversible. When a cell moves its location within a tissue or organism, one side of the cell detaches from the extracellular matrix while the other side extends in the direction of movement, forming new attachments in that direction ([Figure 6.8B](#)). The integrin at the “back” of the cell (away from the direction of movement) is brought into the cytoplasm by endocytosis (see [Key Concept 6.5](#)) so that it can be recycled and used for new attachments at the “front” of the cell. These events are important for cell movement within the developing embryo and for the spread of cancer cells.

6.2 recap

In multicellular organisms, cells arrange themselves into tissues via the processes of cell recognition and cell adhesion. These processes are mediated by membrane-associated proteins and carbohydrates. Cell membrane proteins also interact with the extracellular matrix. Cell junctions assist in strengthening tissues and allow cells to communicate with one another.

learning outcomes

You should be able to:

- Design investigations to analyze the function of proteins and carbohydrates in cell adhesion and cell recognition.
- Compare and contrast the three types of cell junctions found in animals.

1. Describe an experiment showing a role for carbohydrates in cell recognition and adhesion.
2. To which of the three types of cell junctions are plasmodesmata most similar (see [Figure 5.7B](#))?

You have seen how the cell membrane and molecules associated with it facilitate binding between cells and the maintenance of cell adhesion. We'll turn now to another major function of membranes: regulating the substances that enter or leave a cell or organelle.

6.3 Substances Can Cross Membranes by Passive Processes

As you have already learned, cellular membranes have many functions, and control of the cell's internal composition is one of the most important. Biological membranes allow some substances, but not others, to pass through them. This characteristic of membranes is called **selective permeability**. Selective permeability allows the membrane to determine what substances enter or leave a cell or organelle.

selective permeability Allowing certain substances to pass through while other substances are excluded; a characteristic of membranes.

focus your learning

The rate of diffusion of a substance across a membrane is influenced by the size and mass of the diffusing particles, the temperature and the density of the solution, and the size of the concentration gradient.

Osmosis is diffusion of water across a biological membrane.

Proteins that act as channels facilitate diffusion across membranes.

There are two fundamentally different processes by which substances cross biological membranes:

- . The processes of **passive transport** do not require the input of chemical energy to drive them.
- . The processes of **active transport** are driven by chemical energy (metabolic energy).

passive transport Diffusion across a membrane; may or may not require a channel or carrier protein. (Contrast with active transport.)

active transport The energy-dependent transport of a substance across a biological membrane against a concentration gradient—that is, from a region of low concentration (of that substance) to one of high concentration. (See *also* primary active transport, secondary active transport. Contrast with facilitated diffusion, passive transport.)

This section focuses on the passive processes by which substances cross membranes. The energy for the passive transport of a substance comes from the difference between its concentration on one side of the membrane and its concentration on the other—its **concentration gradient**. Passive transport can involve either of two types of diffusion: simple diffusion through the phospholipid bilayer, or facilitated diffusion via channel proteins or carrier proteins.

concentration gradient A difference in concentration of an ion or other chemical substance from one location to another, often across a membrane. (See active transport, facilitated diffusion.)

Animation 6.1 Passive Transport www.Life11e.com/a6.1

Diffusion is the process of random movement toward a state of equilibrium

In a solution, there is a tendency for all of the components to be evenly distributed. You can see this when a drop of food coloring falls into a glass of water. Initially the pigment molecules are very concentrated, but they will move about at random, slowly spreading until the intensity of the color is eventually the same throughout the glass.

A solution in which the solute particles are uniformly distributed is said to be at equilibrium because there will be no future net change in their concentration. Being at equilibrium does not mean that the particles have stopped moving; it just means that they are moving in such a way that their overall distribution does not change.

Diffusion is the process of random movement toward a state of equilibrium. Although the motion of each individual particle is absolutely random, the net movement of particles is directional until equilibrium is reached. Diffusion is thus a net movement from regions of greater concentration to regions of lesser concentration. In a solution with many different substances dissolved in it (solutes), the diffusion of each solute is independent of those of the others. How fast a substance diffuses depends on four factors:

diffusion Random movement of molecules or other particles, resulting in even distribution of the particles when no barriers are present. (Contrast with active transport, diffusion.)

- . The *size and mass* of the molecules or ions: smaller molecules diffuse faster.
- . The *temperature* of the solution: higher temperatures lead to faster diffusion because ions or molecules have more energy, and thus move more rapidly, at higher temperatures.
- . The *density of the solution*: As the density of the solution through which a substance is diffusing increases, the diffusion rate decreases.
- . The *concentration gradient* in the system—that is, the change in solute concentration with distance in a given direction: the greater the concentration gradient, the more rapidly a substance diffuses.

In our example shown above, the gradient is the concentration of food coloring in the droplet when first dropped into the water as compared with the concentration of food coloring in the water on the edge of the glass. When the food coloring is first dropped into the water, there is a high (or steep) concentration gradient. As time passes and the coloring diffuses through the solution, the concentration gradient slowly decreases.

DIFFUSION WITHIN CELLS AND TISSUES

In a small volume such as that inside a cell, solutes distribute themselves rapidly by diffusion. Small molecules and ions may move from one end of a cell to another in a millisecond (10^{-3} s, or one-thousandth of a second). However, the usefulness of diffusion as a transport mechanism declines drastically as distances become greater. In the absence of mechanical stirring, diffusion across more than a centimeter may take an hour or more, and diffusion across meters may take years! Diffusion would not be adequate to distribute materials over the length of a human body, much less that of a larger organism. But within our cells or across layers of one or two cells, diffusion is rapid enough to distribute small molecules and ions almost instantaneously. This is not so when dehydration occurs and the cytoplasm becomes denser as water is lost. Nerve cells in humans are very sensitive to this; when the body becomes dehydrated, unconsciousness may occur because substances important to nerve-cell function diffuse more slowly.

DIFFUSION ACROSS MEMBRANES

In a solution without barriers, all the solutes diffuse at rates determined by temperature, their physical properties, their concentration gradients, and the density of the solution. If a biological membrane divides the solution into separate compartments, then the movement of the different solutes can be affected by the properties of the membrane. The membrane is said to be permeable to solutes that can cross it more or less easily, but impermeable to substances that cannot move across it.

Molecules to which the membrane is impermeable remain in separate compartments, and their concentrations may be different on the two sides of the membrane. Molecules to which the membrane is permeable diffuse from one compartment to the other until their concentrations are equal on both sides of the membrane, and equilibrium is reached. After that point, individual molecules will continue to pass through the membrane, but *there will be no net change in concentration*.

Simple diffusion takes place through the phospholipid bilayer

In [simple diffusion](#), small molecules pass through the phospholipid bilayer of the membrane. A molecule that is itself hydrophobic, and is therefore soluble in lipids, enters the membrane readily and is able to pass through it. The more lipid-soluble the molecule is, the more rapidly it diffuses through the membrane bilayer. This statement holds true over a wide range of molecular weights.

simple diffusion Diffusion that does not involve a direct input of energy or assistance by carrier proteins.
--

By contrast, electrically charged or polar molecules, such as amino acids, sugars, and ions, do not pass readily through a membrane, for two reasons. First, such charged or polar molecules are not very soluble in the hydrophobic interior of the bilayer. Second, such substances form many hydrogen bonds with water and ions in the aqueous environment, be it the cytoplasm or the cell exterior. The multiplicity of these hydrogen bonds prevents the substances from moving into the hydrophobic interior of the membrane. [Figure 6.9](#) summarizes these phenomena.

Figure 6.9 Permeability of Phospholipid Bilayers Small uncharged molecules can diffuse through the membrane, but ions and large polar molecules cannot.

Osmosis is the diffusion of water across membranes

Water molecules pass through specialized channels in membranes (see the opening story) by a diffusion process called ***osmosis**. This completely passive process uses no metabolic energy and depends on the relative concentrations of the water molecules on each side of the membrane. It is important that you remember that in a particular solution, the higher the total solute concentration, the lower the concentration of water molecules. A membrane may allow water but not solutes to pass across it, and in that case, water will diffuse across the membrane toward the side with the higher solute (lower water) concentration.

Three terms are used to compare the solute concentrations of two solutions separated by a membrane:

- **Isotonic** solutions have equal solute concentrations ([Figure 6.10A](#)).

isotonic Having the same solute concentration; said of two solutions. (Contrast with hypertonic, hypotonic.)

Figure 6.10 Osmosis Can Modify the Shapes of Cells In a solution that is isotonic with the cytoplasm **(A)**, a plant or animal cell maintains a consistent, characteristic shape because there is no net movement of water into or out of the cell. In these models, it is assumed that the solutes do not move across the membrane. In a solution that is hypotonic to the cytoplasm **(B)**, water enters the cell. An environment that is hypertonic to the cytoplasm **(C)** results in water leaving the cell.

Q: If you overfertilize the soil of a potted plant, the plant often wilts. Why?

- A **hypotonic** solution has a lower solute concentration than the other solution with which it is being compared (**Figure 6.10B**).

hypotonic Having a lesser solute concentration. Said of one solution in comparing it to another. (Contrast with hypertonic, isotonic.)

- A **hypertonic** solution has a higher solute concentration than the other solution with which it is

being compared ([Figure 6.10C](#)).

hypertonic Having a greater solute concentration. Said of one solution compared with another. (Contrast with hypotonic, isotonic.)

In general, when we discuss tonicity in cells, we refer to the outside solution in comparison to the inside of the cell. Therefore a solution that has a higher concentration of solutes than the concentration inside the cell is hypertonic. To reach equilibrium, water would move out of the cell into the surrounding solution. Water moves from a hypotonic solution across a membrane to a hypertonic solution.

When we say that “water moves,” bear in mind that we are referring to the net movement of water. Since it is so abundant, water is constantly moving through protein channels across the cell membrane into and out of cells. What concerns us here is whether the overall movement is greater in one direction or the other.

The concentration of solutes in the environment determines the direction of [osmosis](#) in all animal cells. A red blood cell takes up water from a solution that is hypotonic to the cell's contents. The cell bursts because its cell membrane cannot withstand the pressure created by the water entry and the resultant swelling. Conversely, the cell shrinks if the solution surrounding it is hypertonic to its contents. The integrity of red and white blood cells is absolutely dependent on the maintenance of a constant solute concentration in the blood plasma: the plasma must be isotonic to the blood cells if the cells are not to burst or shrink. Regulation of the solute concentration of body fluids is thus an important process for organisms without cell walls. Aquatic invertebrates usually have internal solute concentrations that match those of their aqueous environment. However, fish often have a very different internal environment: for example, the environment around a fish living in a freshwater stream is hypotonic to the body fluids inside the fish. Considerable chemical energy must be used to maintain this imbalance.

osmosis (oz mo' sis) [Gk. *osmos*: to push] Movement of water across a differentially permeable membrane, from one region to another region where the water potential is more negative.

Unlike animal cells, the cells of plants, archaea, bacteria, fungi, and some protists have cell walls outside of their cell membrane that limit their volumes and keep them from bursting. Cells with sturdy walls take up a limited amount of water, and in so doing they build up internal pressure against the cell wall, which prevents further water from entering. This pressure within the cell is called [turgor pressure](#). Turgor pressure keeps plants upright (and lettuce crisp) and is the driving force for the enlargement of plant cells. It is a normal and essential component of plant growth. If enough water leaves the cells, turgor pressure drops and the plant wilts.

turgor pressure [L. *turgidus*: swollen] The force exerted by a plant cell against the cell wall when it has taken up water by osmosis. (See pressure potential.)

Turgor pressure reaches about 100 pounds per square inch (0.7 kg/cm^2)—several times greater than the pressure in automobile tires. This pressure is so great that the cells would change shape and detach from one another were it not for adhesive molecules in the plant cell walls and the plasmodesmata linking the cell cytoplasm (see [Key Concept 5.4](#)).

Diffusion may be aided by channel proteins

As we saw earlier, polar or charged substances such as water, amino acids, sugars, and ions do not readily diffuse across membranes. But they can cross the hydrophobic phospholipid bilayer passively (that is, without the input of energy) in one of two ways, depending on the substance:

- **Channel proteins** are integral membrane proteins that form channels across the membrane through which certain substances can pass. Note that these are not channels in the widely used sense of the word (meaning open to the environment like a canal) but tunnels (surrounded by the membrane protein).
- **Carrier proteins** bind substances and speed up their diffusion through the phospholipid bilayer.

channel protein An integral membrane protein that forms an aqueous passageway across the membrane in which it is inserted and through which specific solutes may pass.

carrier proteins Proteins that bind another substance to transport it from one location to another; carriers bind small molecules and transport them across membranes.

Diffusion that is aided by channel proteins or carrier proteins is called **facilitated diffusion**. The substances diffuse according to their concentration gradients, but their diffusion is facilitated by protein channels or carriers. Although these proteins enhance the rate of diffusion, facilitated diffusion, like simple diffusion, does not require any input of energy.

facilitated diffusion Passive movement through a membrane involving a specific carrier protein; does not proceed against a concentration gradient. (Contrast with active transport, diffusion.)

ION CHANNELS

The best-studied channel proteins are the **ion channels**. As you will see in later chapters, the movement of ions across membranes is important in many biological processes such as respiration within the mitochondria, the electrical activity of the nervous system, and the opening of pores in leaves to allow gas exchange with the environment. Several types of ***ion channel** have been identified—each specific for a particular ion. All show the same basic structure of a hydrophilic pore that allows a particular ion to move through its center.

ion channel An integral membrane protein that allows ions to diffuse across the membrane in which it is embedded.

Just as a fence may have a gate that can be opened or closed, most ion channels are gated: they can be opened or closed to ion passage (**Figure 6.11**). A **gated channel** opens when a stimulus causes a change in the three-dimensional shape of the channel. In some cases, this stimulus is the binding of a chemical signal, or **ligand** (see **Figure 6.11**). Channels controlled in this way are called ligand-gated channels. Other channels are mechanically gated and open in response to physical stimuli such as sound waves in the ear. A voltage-gated channel is stimulated to open or close by a change in the voltage (electric charge difference) across the membrane.

Figure 6.11 A Gated Channel Protein Opens in Response to a Stimulus The channel protein has a pore of polar amino acids and water. It is anchored in the hydrophobic bilayer by its outer coating of nonpolar R groups. The protein changes its three-dimensional shape when a stimulus molecule (ligand) binds to it, opening the pore so that specific hydrophilic substances can pass through. Other channels open in response to an electric potential (voltage) or mechanical stimuli.

gated channel A membrane protein that changes its three-dimensional shape, and therefore its ion conductance, in response to a stimulus. When open, it allows specific ions to move across the membrane.

ligand (lig' and) Any molecule that binds to a receptor site of another (usually larger) molecule.

AQUAPORINS FOR WATER

As you saw in the opening story of this chapter, water can cross membranes through protein channels called [aquaporins](#). These channels function as a cellular plumbing system for moving water. The aquaporin channel is highly specific. Water molecules move in single file through the channel, which excludes ions so that the electrical properties of the cell are maintained. Aquaporins were first identified when a protein from red blood cell membranes was inserted into frog oocytes (immature egg cells). The membranes of these cells are normally impermeable to water, but the membranes of the cells treated with aquaporins became much more permeable (**Investigating Life: Aquaporins Increase Membrane Permeability to Water**).

aquaporin A transport protein in plant and animal cell membranes through which water passes in osmosis.

Carrier proteins aid diffusion by binding substances

As we mentioned earlier, another type of facilitated diffusion involves the binding of the transported substance to a membrane protein called a **carrier protein**. Like channel proteins, carrier proteins facilitate the passive diffusion of substances into or out of cells or organelles. Carrier proteins transport polar molecules such as sugars and amino acids.

Glucose is the major energy source for most cells, and living systems require a great deal of it. Glucose is polar and cannot readily diffuse across membranes. Eukaryotic cell membranes contain a carrier protein—the glucose transporter—that facilitates glucose uptake into the cell. Binding of glucose to a specific three-dimensional site on one side of the transporter protein causes the protein to change its shape and release glucose on the other side of the membrane (**Figure 6.12A**). Since glucose is either broken down or otherwise removed almost as soon as it enters a cell, there is almost always a strong concentration gradient favoring glucose entry (that is, a higher concentration outside the cell than inside).

(A) Glucose uptake by the glucose transporter

(B) Gradual saturation of glucose transporters

Figure 6.12 A Carrier Protein Facilitates Diffusion The glucose transporter is a carrier protein that allows glucose to enter the cell at a faster rate than would be possible by simple diffusion. **(A)** The transporter binds to glucose, brings it into the

membrane interior, then changes shape, releasing glucose into the cell cytoplasm. **(B)** The graph shows the rate of glucose entry via a carrier versus the concentration of glucose outside the cell. As the glucose concentration increases, the rate of diffusion increases until the point at which all the available transporters are being used (the system is saturated).

Activity 6.4 Membrane Transport Simulation www.Life11e.com/ac6.4

Transport by carrier proteins is different from simple diffusion. In simple diffusion, the rate of movement depends on the concentration gradient across the membrane. This is also true for carrier-mediated transport, up to a point. In carrier-mediated transport, as the concentration gradient increases, the diffusion rate also increases, but its *rate* of increase slows, and a point is reached at which the diffusion rate becomes constant. At this point, the facilitated diffusion system is said to be *saturated* ([Figure 6.12B](#)). This is explained by the fact that a particular cell has a specific number of carrier protein molecules in its cell membrane.

The rate of diffusion reaches a maximum when all the carrier molecules are fully loaded with solute molecules. Think of waiting for the elevator on the ground floor of a hotel with 50 other people. You can't all get in the elevator (carrier) at once, so the rate of transport (say, ten people at a time) is at its maximum, and the transport system is "saturated." As a consequence, cells that require large amounts of energy, such as muscle cells, have high concentrations of glucose transporters in their membranes so that the maximum rate of facilitated diffusion is greater. Likewise, the human brain has high glucose needs, and the blood vessels that nourish it have high concentrations of glucose transporters.

investigatinglife **Aquaporins Increase Membrane Permeability to Water**

experiment

Original Paper: Preston, G. M., T. P. Carroll, W. B. Guggino and P. Agre. 1992. Appearance of water channels in *Xenopus* oocytes expressing red cell CHIP28 protein. *Science* 256: 385–387.

A protein was isolated from the membranes of cells in which water diffuses rapidly across the membranes. When the protein was inserted into oocytes, which do not normally have it, the water permeability of the oocytes was greatly increased.

HYPOTHESIS ▶ Aquaporin increases membrane permeability to water.

METHOD

CONCLUSION ▶ Aquaporin increases the rate of water diffusion across the cell membrane.

work with the data

Although diffusion can account for limited water movement across cell membranes, simple diffusion seemed unlikely to explain the considerable water movement in kidney and red blood cells. By chance, Peter Agre and his colleagues found a major membrane protein, CHIP28, shared by these two cell types, and hypothesized that it was responsible for cell membrane water transport. So they did a “what if” experiment, taking the mRNA for CHIP28 and injecting it into frog oocytes that do not normally make the protein.

QUESTIONS

1. Frog oocytes in isotonic liquid were injected with either a small amount of water (control) or with CHIP28 mRNA in a small amount of water. The oocytes were then transferred to a hypotonic medium, and changes in relative cell volume were measured by microscopy.

Table A shows the results.

Table A

Time (min)	Cell volume	
	CHIP28 mRNA	Water only (control)
0	1.0	1.0
0.5	1.05	1.0
1	1.15	1.02
1.5	1.23	—
2	1.32	1.02
2.5	1.36	—
3	1.41	1.02
4	(burst)	1.03

Plot the data on a graph of relative cell volume versus time after injection. How do the mRNA and control eggs compare? What explains the increase in the volume of the mRNA-injected oocytes? What explains the situation with both cells at 4 minutes after injection?

2. Water permeability (P_f) was calculated by the rate of osmotic swelling. **Table B** shows the results when increasing amounts of CHIP28 mRNA were injected.

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Table B

Amount of mRNA (ng)	P_f (cm/sec $\times 10^{-4}$) ^a
0	13.7 (3.3)
0.1	50.0 (10.1)
0.5	112 (29.2)
2.0	175 (38.4)
10.0	221 (14.8)

^a Numbers in parentheses indicate $\pm$ standard deviation.

What can you conclude from these data? What statistical test (see Appendix B) would you do to show the significance of your conclusion?

3. To further investigate the role of CHIP28 in water transport, oocytes were given a known inhibitor of protein-mediated water transport, mercuric chloride, and then tested for water permeability with CHIP28 mRNA. Some of the eggs were also treated with mercaptoethanol, a molecule that overcomes the inhibition of water transport by mercuric chloride. The question was, would the inhibitor actually block water transport mediated by CHIP28, and would mercaptoethanol restore transport? The results are shown in **Table C**.

Table C

mRNA injected	Mercuric chloride	Mercaptoethanol	P_f (cm/sec $\times 10^{-4}$)
None	None	None	27.9
None	Yes	None	20.3
None	Yes	Yes	25.4
CHIP28	None	None	210
CHIP28	Yes	None	80.7
CHIP28	Yes	Yes	188

What can you conclude about the molecular nature of water transport mediated by CHIP28 mRNA? What data support your conclusion? Explain all the controls that were done.

The process of diffusion tends to equalize the concentrations of substances outside and inside cells. However, one hallmark of a living cell is that it can have an internal composition quite different from that of its environment. To achieve this, a cell must sometimes move substances against their concentration gradients. This process requires an input of energy and is known as active transport.

6.3 recap

Diffusion is the movement of ions or molecules from a region of greater concentration to a region of lesser concentration. Osmosis is the diffusion of water through a selectively permeable cell membrane. Channel proteins and carrier proteins can facilitate the diffusion of charged and polar substances, including water, across cell membranes.

learning outcomes

You should be able to:

- Predict rates of diffusion of substances under different conditions.
 - Predict the effect of different environmental conditions on the movement of water into and out of living cells.
 - Explain the role of channel proteins in facilitating diffusion across membranes.
-

1. What properties determine whether, and how fast, a substance will diffuse across a membrane?
2. What is the effect on red blood cells if the kidney removes too many ions from the blood and makes it hypotonic to the cells?
3. Cells in the nervous system may have a higher concentration of K^+ ions inside the cell than outside. What is the role of the cell membrane in maintaining this imbalance? How can K^+ membrane channels eliminate this imbalance?

*** connect the concepts** Osmosis plays key roles in plant physiology (e.g., in the root; see [Key Concept 34.1](#)) and in animal physiology (e.g., in the kidney; see [Key Concept 51.1](#)).

*** connect the concepts** Ion channels play an important role in the excitability of nervous tissues. See [Key Concept 45.2](#).

6.4 Active Transport across Membranes Requires Energy

In many biological situations, the concentration of a particular ion or small molecule inside the cell differs from that outside the cell. Such imbalances are maintained by a protein in the cell membrane that moves the substance against its concentration and/or electrical gradient. Movement of molecules or ions against a gradient is called **active transport** because it requires an input of energy. Often the energy source is adenosine triphosphate (ATP), which has chemical energy stored in its terminal phosphate bond. In eukaryotes, ATP is produced in the mitochondria. Energy is released in a hydrolysis reaction that breaks the terminal phosphate bond of ATP, converting it to adenosine diphosphate (ADP). We will detail how ATP provides energy to cells in [Key Concept 8.2](#).

active transport The energy-dependent transport of a substance across a biological membrane against a concentration gradient—that is, from a region of low concentration (of that substance) to one of high concentration. (See *also* primary active transport, secondary active transport. Contrast with facilitated diffusion, passive transport.)

The differences between diffusion and active transport are summarized in [Table 6.1](#).

table 6.1 Membrane Transport Mechanisms			
	Simple diffusion	Simple diffusion (through channel or carrier)	Active transport
Cellular energy required?	No	No	Yes
Driving force	Concentration gradient	Concentration gradient	ATP hydrolysis (against concentration gradient)
Membrane protein required?	No	Yes	Yes
Specificity	No	Yes	Yes

 Animation 6.2 Active Transport www.Life11e.com/a6.2

focus your learning

Active transport requires energy to move a substance against its concentration gradient. Three kinds of membrane proteins are involved in active transport: uniporters, symporters, and antiporters. Primary active transport uses ATP hydrolysis directly to provide the energy for transport, whereas secondary active transport uses an ion concentration gradient that was established by ATP hydrolysis.

Active transport is directional

In diffusion, ions or molecules can move down their concentration gradients in either direction across the cell membrane. In contrast, active transport is directional, and moves a substance either into or out of the cell or organelle, depending on need. There are three kinds of membrane proteins that carry out active transport ([Figure 6.13](#)):

Figure 6.13 Three Types of Proteins for Active Transport Note that in each of the three cases, transport is directional. Symporters and antiporters are examples of coupled transporters. All three types of transporters are coupled to energy sources in order to move substances against their concentration gradients.

- A **uniporter** moves a single substance in one direction. For example, a calcium-binding protein found in the cell membrane and the ER membranes of many cells actively transports Ca^{2+} to locations where it is more highly concentrated, either outside the cell or inside the lumen of the ER.
- A **symporter** moves two substances in the same direction. For example, a symporter in the cells that line the intestine must bind Na^+ in addition to an amino acid in order to absorb amino acids from the intestine.
- An **antiporter** moves two substances in opposite directions, one into the cell (or organelle) and the other out of the cell (or organelle). For example, many cells have a sodium-potassium pump that moves Na^+ out of the cell and K^+ into it.

uniporter [L. *unus*: one + *portal*: doorway] A membrane transport protein that carries a single substance in one direction. (Contrast with antiporter, symporter.)

symporter A membrane transport protein that carries two substances in the same direction. (Contrast with antiporter, uniporter.)

antiporter A membrane transport protein that moves one substance in one direction and another in the opposite direction. (Contrast with symporter, uniporter.)

Symporters and antiporters are also known as **coupled transporters** because they move two substances at once.

coupled transporters Membrane proteins that transport two substances across a membrane, often with the transport of one driving the transport of another.

Different energy sources distinguish different active transport systems

There are two basic types of active transport:

- **Primary active transport** involves the direct hydrolysis of ATP, which provides the energy required for transport.
- **Secondary active transport** does not use ATP directly. Instead, its energy is supplied by an ion concentration gradient established by primary (ATP-driven) active transport.

primary active transport Active transport in which ATP is hydrolyzed, yielding the energy required to transport an ion or molecule against its concentration gradient. (Contrast with secondary active transport.)

secondary active transport A form of active transport that does not use ATP as an energy source; rather, transport is coupled to ion diffusion down a concentration gradient established by primary active transport.

In primary active transport, energy released by the hydrolysis of ATP drives the movement of specific ions against their concentration gradients. For example, we mentioned earlier that concentrations of potassium ions (K^+) inside a cell are often much higher than in the fluid bathing the cell. However, the concentration of sodium ions (Na^+) is often much higher outside the cell. A protein in the cell membrane pumps Na^+ out of the cell and K^+ into the cell against these concentration gradients, ensuring that the gradients are maintained (**Figure 6.14**). This **sodium-potassium (Na^+-K^+) pump** is found in all animal cells. The pump is an integral membrane glycoprotein. It breaks down a molecule of ATP to ADP and a free phosphate ion (P_i) and uses the energy released to bring two K^+ ions into the cell and export three Na^+ ions. The Na^+-K^+ pump is thus an antiporter because it moves two substances in different directions.

Figure 6.14 Primary Active Transport: The Sodium-Potassium Pump In active transport, energy is used to move a solute against its concentration gradient. Here, energy from ATP is used to move Na^+ and K^+ against their concentration gradients.

An important drug used to treat a weak heart inhibits the Na^+-K^+ pump. Digitalis, purified from the foxglove plant, blocks the release of phosphate ions (P_i) from the protein (see [Figure 6.14](#), step 4). This “freezes” the shape of the pump, and it can no longer bind Na^+ . So Na^+ accumulates inside heart cells. This ultimately leads to a greater force of contraction of heart muscle, which aids a patient whose heart is not pumping well.

In secondary active transport, the movement of a substance against its concentration gradient is accomplished using energy “regained” by letting ions move across the membrane with their concentration gradients. Think of it this way: A large dam may prevent a river from flowing. The accumulated water represents energy, and when the water is allowed to flow past the dam, the energy it releases can be used to drive turbines that make electricity. It’s similar for secondary active transport. Consider, for example, the absorption of glucose into the bloodstream from the digestive tract. Once the Na^+-K^+ pump establishes a concentration gradient of sodium ions, the passive diffusion of some Na^+ back into the cell can provide energy for the secondary active transport of glucose into the cell ([Figure 6.15](#)). Secondary active transport aids in the uptake of amino acids and sugars, which are essential raw materials for cell maintenance and growth. Both types of coupled transport proteins—symporters and antiporters—are used for secondary active transport.

Figure 6.15 Secondary Active Transport The Na^+ concentration gradient established by primary active transport by the sodium-potassium pump (left) powers the secondary active transport of glucose (right). A symporter protein couples the movement of glucose across the membrane against its concentration gradient to the passive movement of Na^+ into the cell.

Q: If the $\text{Na}^+\text{-K}^+$ pump is blocked by a drug, how will intercellular concentrations of Na^+ and glucose be affected?

6.4 recap

Active transport across a membrane is directional and requires an input of energy to move substances against their concentration gradients. Active transport allows a cell to maintain small molecules and ions at concentrations very different from those in the surrounding environment.

learning outcomes

You should be able to:

- Compare and contrast diffusion and active transport.
- Explain why active transport requires energy.
- Describe and give examples of the different types of proteins that carry out active transport.

- Differentiate between primary and secondary active transport.
-

1. Why is energy required for active transport?
2. Why is the sodium-potassium ($\text{Na}^+ - \text{K}^+$) pump classified as an antiporter?
3. What are the differences between primary active transport and secondary active transport?
4. What are the similarities and differences between active transport and facilitated diffusion?

We have examined a number of passive and active ways in which ions and small molecules can enter and leave cells. But what about large molecules such as proteins? Many proteins are so large that they diffuse very slowly, and their bulk makes it difficult for them to pass through the phospholipid bilayer. A completely different mechanism is needed to move intact large molecules across membranes.

6.5 Large Molecules Enter and Leave a Cell through Vesicles

Macromolecules such as proteins, polysaccharides, and nucleic acids are simply too large and too charged or polar to pass through biological membranes. This is actually fortunate—think of the consequences if such molecules diffused out of cells: A red blood cell would not retain its hemoglobin! As you saw in [Chapter 5](#), the development of a selectively permeable membrane was essential for the functioning of the first cells when life on Earth began. The interior of a cell can be maintained as a separate compartment with a different composition from that of the exterior environment, which is subject to abrupt changes. However, cells must sometimes take up or secrete (release to the external environment) intact large molecules. In [Key Concept 5.3](#) we described phagocytosis, the mechanism by which solid particles can be brought into the cell by means of vesicles that pinch off from the cell membrane. The general terms for the mechanisms by which substances enter and leave the cell via membrane vesicles are endocytosis and exocytosis.

focus your learning

Three types of endocytosis occur in cells.

Cells take in specific molecules from the environment through receptor-mediated endocytosis.

Exocytosis is the process by which substances are secreted by a cell.

Animation 6.3 **Endocytosis and Exocytosis** www.Life11e.com/a6.3

Macromolecules and particles enter the cell by endocytosis

Endocytosis is a general term for a group of processes that bring small molecules, macromolecules, large particles, and even small cells into the eukaryotic cell ([Figure 6.16A](#)). We described an example of endocytosis earlier in the chapter, involving integrins (see [Figure 6.8](#)). Generally, there are three types of endocytosis: phagocytosis, pinocytosis, and receptor-mediated endocytosis. In all three, the cell membrane invaginates (folds inward), forming a small pocket around materials from the environment. The pocket deepens, forming a vesicle. This vesicle separates from the cell membrane and migrates with its contents to the cell's interior.

endocytosis A process by which liquids or solid particles are taken up by a cell through invagination of the plasma membrane. (Contrast with exocytosis.)

(A) Endocytosis

(B) Exocytosis

Figure 6.16 Endocytosis and Exocytosis Endocytosis **(A)** and exocytosis **(B)** are used by eukaryotic cells to take up and release fluids, large molecules, and particles. Smaller cells, such as invading bacteria, can be taken up by endocytosis.

Media Clip 6.1 An Amoeba Eats by Phagocytosis www.Life11e.com/mc6.1

In **phagocytosis** (“cellular eating”), part of the cell membrane engulfs large particles or even entire cells. Unicellular protists use phagocytosis for feeding, and some white blood cells use phagocytosis to defend the body by engulfing foreign cells and substances. The food vacuole or phagosome that forms usually fuses with a lysosome, where its contents are digested (see [Figure 5.10](#)).

In **pinocytosis** (“cellular drinking”), vesicles also form. However, these vesicles are smaller, and the process operates to bring fluids and dissolved substances into the cell. Like phagocytosis, pinocytosis can be relatively nonspecific regarding what it brings into the cell. For example, pinocytosis occurs constantly in the endothelium, the single layer of cells that separates a tiny blood capillary from the surrounding tissue. Pinocytosis allows cells of the endothelium to rapidly acquire fluids and dissolved solutes from the blood.

In **receptor-mediated endocytosis**, molecules at the cell surface recognize and trigger the uptake of specific materials.

phagocytosis The process by which a cell uses its cell membrane to enclose and engulf a macromolecule or particle in the extracellular environment.

pinocytosis Endocytosis by a cell of liquid containing dissolved substances.

receptor-mediated endocytosis Endocytosis initiated by macromolecular binding to a specific membrane receptor.

Let's take a closer look at this last process.

Receptor-mediated endocytosis is highly specific

Receptor-mediated endocytosis is used by animal cells to capture specific macromolecules from the cell's environment. This process depends on [receptor proteins](#), which are proteins that can bind to specific molecules within the cell or in the cell's external environment. In receptor-mediated endocytosis, the receptors are integral membrane proteins located at particular regions on the extracellular surface of the cell membrane. These membrane regions are called coated pits because they form slight depressions in the cell membrane and their cytoplasmic surfaces are coated by other proteins, such as clathrin. The uptake process is similar to that in phagocytosis.

receptor protein A protein that can bind to a specific molecule, or detect a specific stimulus, within the cell or in the cell's external environment.

When a receptor protein binds to its specific ligand (in this case, the macromolecule to be taken into the cell), its coated pit invaginates and forms a coated vesicle around the bound macromolecule. The clathrin molecules strengthen and stabilize the vesicle, which carries the macromolecule away from the cell membrane and into the cytoplasm ([Figure 6.17](#)). Once inside, the vesicle loses its clathrin coat and may fuse with a lysosome, where the engulfed material is digested (by the hydrolysis of polymers to monomers) and the products are released into the cytoplasm. Because of its specificity for particular macromolecules, receptor-mediated endocytosis is an efficient method of taking up substances that may exist at low concentrations in the cell's environment.

Figure 6.17 Receptor-Mediated Endocytosis The receptor proteins in a coated pit bind specific macromolecules, which are then carried into the cell by a coated vesicle.

Receptor-mediated endocytosis is the method by which cholesterol is taken up by most mammalian cells. Water-insoluble cholesterol and triglycerides are packaged by liver cells into lipoprotein particles. Most of the cholesterol is packaged into a type of lipoprotein particle called low-density lipoprotein, or LDL, which is circulated via the bloodstream. When a particular cell requires cholesterol, it produces specific LDL receptors, which are inserted into the cell membrane in clathrin-coated pits. Binding of LDLs to the receptor proteins triggers the uptake of the LDLs via receptor-mediated endocytosis. Within the resulting vesicle, the LDL particles are freed from the receptors. The receptors segregate to a region that buds off and forms a new vesicle, which is recycled to the cell membrane. The freed LDL particles remain in the original vesicle, which fuses with a lysosome. There, the LDLs are digested and the cholesterol made available for cell use.

In healthy individuals, the liver takes up unused LDLs for recycling. People with the inherited disease familial hypercholesterolemia have a deficient LDL receptor in their livers. This prevents receptor-mediated endocytosis of LDLs, resulting in dangerously high levels of cholesterol in the blood. The cholesterol builds up in the arteries that nourish the heart and causes heart attacks. In extreme cases where only the deficient receptor is present, children and teenagers can have severe cardiovascular disease.

Exocytosis moves materials out of the cell

Exocytosis is the process by which materials packaged in vesicles are secreted from a cell when the vesicle membrane fuses with the cell membrane (**Figure 6.16B**). This fusing allows the vesicle contents to be released into the environment, and the vesicle membrane is smoothly incorporated into the cell membrane. In another form of exocytosis, the vesicle touches the cell membrane and a pore forms, releasing the vesicle's contents. There is no membrane fusion in

this process, termed “kiss and run.” We saw an example of exocytosis in describing sweat glands at the start of the chapter.

exocytosis A process by which a vesicle within a cell fuses with the plasma membrane and releases its contents to the outside. (Contrast with endocytosis.)

[Table 6.2](#) summarizes examples of endocytosis and exocytosis.

table 6.2 Endocytosis and Exocytosis	
Type of process	Example
Endocytosis	
Receptor-mediated endocytosis	Specific uptake of large molecules (e.g., LDL)
Pinocytosis	Nonspecific uptake of extracellular fluid (e.g., fluids and dissolved substances from blood)
Phagocytosis	Nonspecific uptake of large undissolved particles (e.g., invading bacteria by cells of the immune system)
Exocytosis	
Release of large molecules	Vesicle fusion with cell membrane (e.g., digestive enzymes in the pancreas)
Release of small molecules	Vesicle fusion with cell membrane (e.g., neurotransmitters at the synapse)

6.5 recap

Endocytosis and exocytosis are the processes by which large particles and molecules are transported into and out of the cell. Endocytosis may be mediated by a receptor protein in the cell membrane.

learning outcomes

- You should be able to:
- Compare and contrast the three types of endocytosis.
 - Describe the process of receptor-mediated endocytosis.
 - Provide examples of processes that involve endocytosis and/or exocytosis.

1. What are the differences between phagocytosis and pinocytosis?
2. Describe receptor-mediated endocytosis and give an example of a process involving this phenomenon.
3. [Key Concept 27.2](#) describes the diatoms, which are protists that have complex glassy structures in their cell walls (see [Figure 27.8](#) and the photo below of eight diatom cells inside their ornate cell walls). These structures form within the Golgi apparatus. How do they reach the cell wall without having to pass through a membrane?

investigatinglife

What is the importance of aquaporin membrane channels?

There are a dozen genes encoding aquaporins in humans, each channel having its particular location in the body. Genetic deficiency resulting in a lack of one of the aquaporins can have significant consequences. For example, one of the aquaporins occurs in the part of the kidney where water is removed from the developing urine and returned to the blood. When this aquaporin is absent, there is more water in urine and the person urinates more and more often; bedwetting is a common result. In plants, aquaporins occur in the cell membrane and tonoplast (membrane that encloses the vacuole). In the cell membranes of root cells, aquaporins form channels for water on its way from the soil to the interior tissues of the root, from which it is transported to the rest of the plant. In the vacuole, aquaporin channels are important in the organelle swelling, resulting in turgor pressure, which is important in plant organ structure and plant cell expansion. All of these aquaporins, and those of other organisms, share a common structure that spans the cell membrane and has a channel through which water molecules pass in single file.

Future directions

A fascinating role for aquaporins is not just in the transport of water across membranes, but in the accompanying transport of substances dissolved in it. For example, in plants boron is an important nutrient, and it does not diffuse efficiently across membranes. Soil water containing boron ions passes readily into plants through aquaporin channels. Even gases such as CO_2 may pass in and out of cells via aquaporins while dissolved in water. Efforts are under way to insert aquaporins into synthetic membranes used for industrial applications. Because aquaporins allow only water and low concentrations of ions to pass through, such membranes could be used to purify contaminated fresh water, or to desalinate water, which as you know has very high ion concentrations. Aquaporins are expressed in skin, where they play a role in keeping the skin moist. This is also a goal of some cosmetics (moisturizers) and has led to a search for, and patenting of, small molecules that stimulate aquaporins. These molecules are components of some widely marketed skin creams.

6.1 Biological Membranes Are Lipid–Protein Bilayers

- Biological membranes consist of lipids, proteins, and carbohydrates. The [fluid mosaic model](#) of membrane structure describes a phospholipid bilayer in which proteins can move about within the plane of the membrane. **!Review Activity 6.1**

fluid mosaic model A molecular model for the structure of biological membranes consisting of a fluid phospholipid bilayer in which suspended proteins are free to move in the plane of the bilayer.

- The two layers of a membrane may have different properties because of their different lipid compositions. Animal cell membranes may contain high concentrations of cholesterol (up to 25%). **!Review Activity 6.2**
- The properties of membranes also depend on the [integral membrane proteins](#) and [peripheral membrane proteins](#) associated with them. Some proteins, called **transmembrane** proteins, span the membrane. **!Review Focus: Key Figure 6.1**

integral membrane proteins Proteins that are at least partially embedded in the plasma membrane. (Contrast with peripheral membrane proteins.)

peripheral membrane proteins Proteins associated with but not embedded within the plasma membrane. (Contrast with integral membrane proteins.)

- Carbohydrates, attached to proteins in [glycoproteins](#) or to phospholipids in **glycolipids**, project from the external surface of the cell membrane and function as recognition signals.

glycoprotein A protein to which sugars are attached.

- Membranes are not static structures, but are constantly forming, exchanging components, and breaking down.

6.2 Cell Membrane Is Important in Cell Adhesion and Recognition

- In order for cells to assemble into tissues, they must recognize and adhere to one another. [Cell recognition](#) and [cell adhesion](#) depend on membrane-associated proteins and carbohydrates. **!Review Figure 6.6**

cell recognition Binding of cells to one another mediated by membrane proteins or carbohydrates.

cell adhesion The binding of one cell to another, often mediated by noncovalent forces.

- Adhesion can involve binding between identical ([homotypic](#)) or different (**heterotypic**) molecules on adjacent cells.

homotypic Pertaining to adhesion of cells of the same type.

- **Cell junctions** connect adjacent cells. In some animal cells, **tight junctions** prevent the passage of molecules through the intercellular spaces between cells, and they restrict the migration of membrane proteins over the cell surface. **Desmosomes** cause cells to adhere firmly to one another. **Gap junctions** provide channels for communication between adjacent cells. **!Review Figure 6.7, Activity 6.3**

cell junctions Specialized structures associated with the plasma membranes of epithelial cells. Some contribute to cell adhesion, others to intercellular communication.

tight junction A junction between epithelial cells in which there is no gap between adjacent cells.

desmosome (dez' mo sowm) [Gk. *desmos*: bond + *soma*: body] An adhering junction between animal cells.

gap junction A 2.7-nanometer gap between cell membranes of two animal cells, spanned by protein channels. Gap junctions allow chemical substances or electrical signals to pass from cell to cell.

- **Integrins** mediate the attachment of animal cells to the extracellular matrix and to each other. Detachment and recycling of integrins allow cells to move. **!Review Figure 6.8**

integrin In animals, a transmembrane protein that mediates the attachment of epithelial cells to the extracellular matrix.

6.3 Substances Can Cross Membranes by Passive Processes

!See Animation 6.1

- Membranes exhibit **selective permeability**, regulating which substances pass through them. Substances can cross the membrane by either **passive transport**, which requires no input of chemical energy, or by **active transport**, which uses chemical energy. **!Review Figure 6.9**

selective permeability Allowing certain substances to pass through while other substances are excluded; a characteristic of membranes.

passive transport Diffusion across a membrane; may or may not require a channel or carrier protein. (Contrast with active transport.)

active transport The energy-dependent transport of a substance across a biological membrane against a concentration gradient—that is, from a region of low concentration (of that substance) to one of high concentration. (See *also* primary active transport, secondary active transport. Contrast with facilitated diffusion, passive transport.)

- **Diffusion** is the movement of a solute from a region of higher concentration to a region of lower concentration. Equilibrium is reached when there is no further net change in concentration.

diffusion Random movement of molecules or other particles, resulting in even distribution of the particles when no barriers are present. (Contrast with active transport, diffusion.)

- In **osmosis**, water diffuses across a membrane from a region of higher water concentration to a region of lower water concentration.

osmosis (oz mo' sis) [Gk. *osmos*: to push] Movement of water across a differentially permeable membrane, from one region to another region where the water potential is more negative.

- In an **isotonic** environment, total solute concentrations on both sides of the cell membrane are equal. If the solution surrounding a cell is **hypotonic** to the cell interior, more water enters the cell than leaves it, causing it to swell. In plant cells, this contributes to **turgor pressure**. In a **hypertonic** solution, more water leaves the cell than enters it, causing it to shrivel. **!Review Figure 6.10**

isotonic Having the same solute concentration; said of two solutions. (Contrast with hypertonic, hypotonic.)

hypotonic Having a lesser solute concentration. Said of one solution in comparing it to another. (Contrast with hypertonic, isotonic.)

turgor pressure [L. *turgidus*: swollen] The force exerted by a plant cell against the cell wall when it has taken up water by osmosis. (See pressure potential.)

hypertonic Having a greater solute concentration. Said of one solution compared with another. (Contrast with hypotonic, isotonic.)

- A substance can diffuse passively across a membrane by either **simple diffusion** or **facilitated diffusion**, via a **channel protein** or a carrier protein.

simple diffusion Diffusion that does not involve a direct input of energy or assistance by carrier proteins.

facilitated diffusion Passive movement through a membrane involving a specific carrier protein; does not proceed against a concentration gradient. (Contrast with active transport, diffusion.)

channel protein An integral membrane protein that forms an aqueous passageway across the membrane in which it is inserted and through which specific solutes may pass.

- **Ion channels** are membrane proteins that allow the rapid facilitated diffusion of ions through membranes. **Gated channels** can be opened or closed by chemical **ligands**, or changes in membrane voltage, or mechanical stimuli. **!Review Figure 6.11**

ion channel An integral membrane protein that allows ions to diffuse across the membrane in which it is embedded.

gated channel A membrane protein that changes its three-dimensional shape, and therefore its ion conductance, in response to a stimulus. When open, it allows specific ions to move across the membrane.

ligand (lig' and) Any molecule that binds to a receptor site of another (usually larger) molecule.

- **Aquaporins** are water channels. **Review Investigating Life: Aquaporins Increase Membrane Permeability to Water**

aquaporin A transport protein in plant and animal cell membranes through which water passes

in osmosis.

- **Carrier proteins** bind to polar molecules such as sugars and amino acids and transport them across the membrane. The maximum rate of this type of facilitated diffusion is limited by the number of carrier (transporter) proteins in the membrane. **Review Figure 6.12, Activity 6.4**

carrier proteins Proteins that bind another substance to transport it from one location to another; carriers bind small molecules and transport them across membranes.

6.4 Active Transport across Membranes Requires Energy

!See Animation 6.2

- **Active transport** requires the use of chemical energy to move substances across membranes against their concentration or electrical gradients. Active transport proteins may be uniporters, symporters, or **antiporters**. **!Review Figure 6.13**

active transport The energy-dependent transport of a substance across a biological membrane against a concentration gradient—that is, from a region of low concentration (of that substance) to one of high concentration. (See *also* primary active transport, secondary active transport. Contrast with facilitated diffusion, passive transport.)

antiporter A membrane transport protein that moves one substance in one direction and another in the opposite direction. (Contrast with symporter, uniporter.)

- In **primary active transport**, energy from the hydrolysis of ATP is used to move ions into or out of cells. The **sodium–potassium pump** is an important example. **!Review Figure 6.14**

primary active transport Active transport in which ATP is hydrolyzed, yielding the energy required to transport an ion or molecule against its concentration gradient. (Contrast with secondary active transport.)

sodium–potassium ($\text{Na}^+ - \text{K}^+$) pump Antiporter responsible for primary active transport; it pumps sodium ions out of the cell and potassium ions into the cell, both against their concentration gradients. Also called a sodium–potassium ATPase.

- **Secondary active transport** couples the passive movement of one substance down its concentration gradient to the movement of another substance against its concentration gradient. Energy from ATP is used indirectly to establish the concentration gradient that results in the movement of the first substance. **Review Figure 6.15**

secondary active transport A form of active transport that does not use ATP as an energy source; rather, transport is coupled to ion diffusion down a concentration gradient established by primary active transport.

6.5 Large Molecules Enter and Leave a Cell through Vesicles

!See Animation 6.3

- **Endocytosis** is the transport of small molecules, macromolecules, large particles, and

small cells into eukaryotic cells via invagination of the cell membrane and the formation of vesicles. [Phagocytosis](#) and [pinocytosis](#) are types of endocytosis. **!Review Figure 6.16A**

endocytosis A process by which liquids or solid particles are taken up by a cell through invagination of the plasma membrane. (Contrast with exocytosis.)

phagocytosis The process by which a cell uses its cell membrane to enclose and engulf a macromolecule or particle in the extracellular environment.

pinocytosis Endocytosis by a cell of liquid containing dissolved substances.

- In [exocytosis](#), materials in vesicles are secreted from the cell when the vesicles fuse with the cell membrane. **!Review Figure 6.16B**

exocytosis A process by which a vesicle within a cell fuses with the plasma membrane and releases its contents to the outside. (Contrast with endocytosis.)

- In [receptor-mediated endocytosis](#), a specific [receptor protein](#) on the cell membrane binds to a particular macromolecule. **!Review Figure 6.17**

receptor-mediated endocytosis Endocytosis initiated by macromolecular binding to a specific membrane receptor.

receptor protein A protein that can bind to a specific molecule, or detect a specific stimulus, within the cell or in the cell's external environment.

Review

.1 The degree of a membrane's fluidity is influenced by lipid composition and temperature.

Original Paper: Cossins, A. R. and C. L. Prosser. 1978. Evolutionary adaptation of membranes to temperature. *Proceedings of the National Academy of Sciences USA*. 75: 2040–2043.

Fish are poikilotherms, animals having body temperatures that change with their environment. Depending on where you go in the world, you can find fish at all extremes of body temperature. Desert pupfish native to desert springs in California and Mexico tolerate temperatures as high as 42°C. At the other extreme is the Arctic sculpin, which can tolerate water temperatures as low as –2°C. Goldfish live at more moderate temperatures ranging from 5°C to 25°C.

A research group saw this range as an interesting opportunity to run a comparative study of the fluidity and composition of cell membranes. They included rats and hamsters in the study, because rats maintain a constant body temperature of 37°C and represent the high end of the temperature range. The researchers kept each animal at a specific temperature for several days. Arctic sculpin were held at 0°C. One group of goldfish was held at 5°C, and another was held at 25°C. Desert pupfish were held at 34°C, and rats were held at normal room temperature, 21°C. The same neuronal cells were removed from each animal and membranes isolated from these cells. This gave the researchers a set of cell membranes representing environmental temperatures ranging from 0°C to 37°C.

The researchers then added a fluorescent molecule to each of the membranes and incubated them at 20°C. They measured fluorescence and plotted these data against the animal's body temperature, as shown in the graph at right. (Each point represents a single animal.) Fluorescence is inversely related to the movement of the molecules within the membranes. A higher value means less movement of the fluorescent probe and therefore a less fluid membrane.

The table below shows the ratio of saturated to unsaturated fatty acids in the phospholipid phosphatidyl choline for various species in the study.

Ratio of saturated to unsaturated fatty acids				
Arctic sculpin 0°C	Goldfish 5°C	Goldfish 25°C	Desert pupfish 34°C	Rat 37°C
0.593	0.659	0.817	0.990	1.218

Questions

1. What do the data in the graph indicate about the relative fluidity of cell membranes in different species when measured under the same temperature conditions? Is a trend apparent? Explain.
2. Temperature affects membrane fluidity. According to the data, what else influences membrane fluidity?
3. Considering your answer to Question 2, explain how and why this factor affects membrane fluidity.
4. Suppose you isolated cell membranes from an animal and measured the fluorescence of a membrane probe in the same way that these researchers did. If the fluorescence was found to be 0.27, and assuming that the movement of the fluorescent probe is only affected by fatty acid saturation/unsaturation, what can you predict about the ratio of saturated to unsaturated fatty acids in ethanolamine phospholipids present in membranes of this animal? Express your answer to the hundredths place.

A Signal for Bonding

Prairie voles (*Microtus ochrogaster*) are small rodents that live in temperate climates, where they dig tunnels in fields. When a male prairie vole encounters a female, the female enters her reproductive cycle and mating (which can take hours) often ensues. After mating the pair stays together, building a nest and raising their pups. The bond between the two voles is so strong that they stay together for life. Contrast this behavior with that of the montane vole (*M. montanus*), which is closely related to the prairie vole and lives in the hills not far away. In this species, mating is quick, and afterward the pair separates. The male looks for new mates and the female abandons her young soon after they are born.

The reason for these dramatic behavioral differences lies in the brains of these two species. When prairie voles mate, the brains of both males and females release specific peptides consisting of nine amino acids. In females, the peptide is oxytocin; in males, it is vasopressin. The peptides circulate in the bloodstream and reach all tissues in the body, but they bind to only a few cell types. These cells have surface proteins called receptors, to which the peptides specifically bind, like a key inserting into a lock.

The binding of peptide to receptor causes the receptor, which extends across the cell membrane, to change shape. Within the cytoplasm, this change sets off a series of events that ultimately result in changes in behavior. The receptors for oxytocin and vasopressin in prairie voles are most concentrated in the regions of the brain that are responsible for behaviors such as bonding and caring for young. In montane voles, there are far fewer receptors for these peptides, and as a result, fewer bonding and caring behaviors. Clearly, oxytocin and vasopressin are signals that induce these behaviors.

Intercellular signaling is a hallmark of multicellular organisms. A cell's response to a signal molecule takes place in three sequential steps. First, the signal binds to a receptor in the cell, often embedded in the outside surface of the cell membrane. Second, signal binding conveys a message to the cell. Third, the cell changes its activity in response to the signal. In a multicellular organism, these steps lead to changes in that organism's functioning, with signaling allowing different types of cells and tissues to work together.

Is oxytocin the “trust” signal in humans?

7.1 Signals and Signaling Affect Cell Function

Both prokaryotic and eukaryotic cells process information from their environments. This information can be in the form of a physical stimulus, such as the light reaching your eyes as you read this book, or chemicals that bathe a cell, such as the carbohydrate lactose in the solution around bacteria. A signal may come from outside the organism, such as the scent of a female moth seeking a mate in the dark, or from a neighboring cell within the organism, such as the liver, where signals from other organs cause liver cells to regulate their uptake or release of glucose.

focus your learning

Chemical signals that target cells can be classified according to signal source and mode of signal delivery.

A signal transduction pathway includes a signal, a receptor, and a response

Not all cells respond to a signal, because some lack the ability to receive the signal.

The presence of a signal does not always lead to a response; a cell does not respond to every signal, just as you are not paying close attention to every stimulus in your environment as you read this. To respond to a signal, a cell must have a specific receptor that can detect it and a way to use that information to influence cellular processes. A [signal transduction pathway](#) is a sequence of molecular events and chemical reactions that lead to a cell's response to a signal. Signal transduction pathways vary greatly in their details, but every such pathway involves a signal, a receptor, and a response. This section will provide a brief overview of signal transduction. We'll consider receptors in [Key Concept 7.2](#), and other aspects of signal transduction in [Key Concepts 7.3](#) and [7.4](#).

signal transduction pathway The series of biochemical steps whereby a stimulus to a cell (such as a hormone or neurotransmitter binding to a receptor) is translated into a response of the cell.

Cells receive several types of signals

The environment is full of signals. For example, our sense organs allow us to respond to light (a physical signal), or odors and tastes (chemical signals). Bacteria and protists can respond to small chemical changes in their surroundings. Plants respond to light as a signal as well as an energy source, for example, by growing toward the source of light. A cell that is deep inside a large multicellular organism and far away from the exterior environment receives signals from neighboring cells and the surrounding extracellular fluids. In multicellular organisms, chemical signals are often made in one part of the body and arrive at target cells by local diffusion or by circulation in the blood or the plant vascular system. Chemical cell signals are usually present in tiny concentrations (as low as 10^{-10} M) (see [Chapter 2](#) for an explanation of molar concentrations) and differ in their sources and mode of delivery ([Figure 7.1](#)):

(A) Cell signaling on the local level

(B) Cell signaling from a distance

Figure 7.1 Chemical Signaling Systems **(A)** A signal molecule can diffuse to and act on the cell that produces it, an adjacent cell, or a nearby cell. **(B)** Hormones are chemical signals that act on distant cells and must be transported by the organism's circulatory system.

 Activity 7.1 Chemical Signaling Systems www.Life11e.com/ac7.1

Autocrine signals diffuse to and affect the cells that make them. For example, many tumor cells reproduce uncontrollably because they both make, and respond to, signals that stimulate cell division.

Juxtacrine signals affect only cells right next to and in contact with the cell producing the signal. This type of signaling is especially common during development, when cells are in groups and changing to become specialized.

Paracrine signals diffuse to and affect nearby cells. An example occurs in inflammation when the skin is cut. Signals from skin cells are sent to nearby blood cells to aid in healing (see [Key Concept 41.2](#)).

Signals that travel through the circulatory systems of animals or the vascular systems of plants are generally called **hormones**.

autocrine A chemical signal that binds to and affects the cell that makes it. (Contrast with paracrine.)

juxtacrine A mode of cell communication where the cell producing a signal is in contact with the cell bearing the receptor for that signal.

paracrine [Gk. *para*: near] Pertaining to a chemical signal, such as a hormone, that acts locally, near the site of its secretion. (Contrast with autocrine.)

hormone (hore' mone) [Gk. *hormon*: to excite, stimulate] A chemical signal produced in minute amounts at one site in a multicellular organism and transported to another site where it acts on target cells.

A signal transduction pathway involves a signal, a receptor, and responses: **Overview**

As you saw in the opening story, the elements of a signal transduction pathway are a signal, a receptor, and a response ([Figure 7.2](#)). For the information from a signal to be transmitted to a cell, the target cell must be able to receive the signal and respond to it. This is the job of receptors. All cells may be exposed to a chemical signal, but most cells in the organism may not be able to respond to it. *Only cells with the appropriate receptors can respond.*

Figure 7.2 A Signal Transduction Pathway This general pathway is common to many cells and situations. The ultimate effects on the cell are either short-term or long-term molecular changes, or both.

The response can involve enzymes, which catalyze biochemical reactions, and transcription factors, which are proteins that turn the expression of particular genes on and off. An important feature of signal transduction is that the activities of specific enzymes and transcription factors are regulated: they are either activated or inactivated to bring about cellular changes (see [Figure 7.2](#)). For example, an enzyme may be activated by the addition of a phosphate group (phosphorylation) to a particular site on the protein, thereby changing the enzyme's shape (see [Figure 3.13B](#)) and exposing its active site. The activity of a protein can also be regulated by mechanisms that control its location in the cell. For example, a transcription factor located in the cytoplasm is inactive because it is separated from the genetic material in the nucleus; a signal transduction pathway may result in the transport of the factor to the nucleus, where it can affect gene expression.

In this chapter we'll consider signal transduction pathways in isolation from one another. In life, however, signal transduction pathways are often interconnected. A great deal of **crosstalk**—interactions between different signal transduction pathways—is common. For example, a single activated protein (receptor or enzyme) might activate enzymes or transcription factors in multiple pathways, leading to multiple responses to a single stimulus. Multiple signal transduction pathways might converge on a single transcription factor, allowing the transcription of a single gene to be adjusted in response to several different signals. Crosstalk can also result in the activation of one pathway and the inhibition of another. The phenomenon of crosstalk inside the cell is analogous to the "crosstalk" that occurs at the level of the whole body. For

example, in your limbs you have opposing muscles. When you bend your elbow, you contract one set of muscles and relax the opposing muscles, so that your arm will bend. Because of crosstalk, biologists often refer to “signaling networks” rather than signal transduction pathways, reflecting the high degree of complexity in cellular signaling.

crosstalk Interactions between different signal transduction pathways.

7.1 recap

Cells are constantly exposed to molecular signals that can come from the external environment or from within the body of a multicellular organism. To respond to a signal, the cell must have a specific receptor that detects the signal and activates some type of cellular response. Signal transduction pathways involve regulation of enzymes and transcription factors, and crosstalk often occurs between pathways.

learning outcomes

You should be able to:

- Use the source and distribution mechanism of a signal to identify the type.
- Give an example of how a particular type of signal (autocrine, juxtacrine, paracrine, or hormone) functions in an organism.
- Explain how specificity is achieved in a signal transduction pathway.
- Compare cells found in the same organism that can and cannot respond to a specific chemical signal.

1. Under what conditions would autocrine signaling be most advantageous for a cell?
2. How are hormones delivered to target cell receptors?
3. All cells have the potential to respond to all signals in an organism. What makes signaling specific?

The general features of signal transduction pathways described in this section will recur in more detail throughout the chapter. First, let's consider more closely the nature of the receptors that bind signal molecules.

7.2 Receptors Bind Signals to Initiate a Cellular Response

Any given cell in a multicellular organism is bombarded with many signals. However, it responds to only some of them, because no cell makes receptors for all signals. A [receptor](#) protein recognizes its signal very specifically, in much the same way that a membrane transport protein recognizes and binds to the substance it transports. This specificity ensures that only those cells that make a specific receptor will respond to a given signal.

receptor See receptor protein, sensor.

focus your learning

Cells make specific receptor proteins that recognize only the signals to which they respond.

The binding of a chemical signal (called a ligand) with its receptor is reversible and is measured by a dissociation constant.

Intracellular receptors are located inside the cell, where they interact with physical signals such as light or with chemical signals that diffuse across the cell membrane.

Receptors that recognize chemical signals have specific binding sites

A [ligand](#) is a specific chemical signal molecule that fits into a three-dimensional site on its protein receptor ([Figure 7.3A](#)). Binding of the signaling ligand causes the receptor protein to change its three-dimensional shape, and that conformational change initiates a cellular response. The ligand does not contribute further to this response. In fact, the ligand is usually not changed; its role is purely to “knock on the door.”

ligand (lig' and) Any molecule that binds to a receptor site of another (usually larger) molecule.

(A) The signal, adenosine, binding to its receptor

(B) Chemical similarity between caffeine and adenosine

Figure 7.3 A Signal and Its Receptor (A) The adenosine 2A receptor occurs in the human brain, where it is involved in inhibiting active wakefulness. **(B)** Adenosine is the normal (endogenous) ligand for the receptor. Caffeine has a structure similar to that of adenosine and can act as an antagonist that binds the receptor and prevents its normal functioning.

Is the binding of adenosine and caffeine covalent or noncovalent? Explain your answer.

Q: The sensitivity of a cell to a signal is determined in part by the affinity of the cell's receptors for the signal ligand—the likelihood that the receptor will bind to the ligand at any given ligand concentration. Receptors (R) bind to their ligands (L) according to chemistry's law of mass action. This means that the binding is reversible:

For most ligand–receptor complexes (RL), binding is favored. Reversibility is important, however, because if the ligand were never released, the receptor would be continuously stimulated and the cell would never stop responding.

As with any reversible chemical reaction, the binding and dissociation processes each have a rate constant, here designated k_1 and k_2 :

A rate constant relates the rate of a reaction to the concentration(s) of the reactant(s):

$$\text{Rate of binding} = k_1 [R] [L] \quad (7.4)$$

$$\text{Rate of dissociation} = k_2 [RL] \quad (7.5)$$

where “[]” indicates the concentration of the substance inside the brackets. Binding of a receptor to a ligand is reversible, and when equilibrium is reached the rate of binding equals the rate of dissociation:

$$k_1 [R] [L] = k_2 [RL] \quad (7.6)$$

If this is rearranged, we get:

$$\frac{[R] [L]}{[RL]} = \frac{k_2}{k_1} = K_D \quad (7.7)$$

K_D , the **dissociation constant**, is a measure of the affinity of the receptor for its ligand. The lower the K_D , the higher the affinity of the ligand for its receptor. Some receptors have very low K_D values, which allows them to bind their ligands at very low ligand concentrations; other receptors have higher K_D values and need more ligand to be present to set off their signal transduction pathways.

K_D See dissociation constant.

dissociation constant (K_D) A type of equilibrium constant measuring the tendency of a two substances that are bound together to separate into the two smaller components. In cell signaling, the two substances are a ligand and receptor.

An entire field of biology and medicine—called pharmacology—is devoted to the study of drugs. These molecules are usually thought of as synthetic, but some are natural substances, such as caffeine (see [Figure 7.3B](#)). Drugs function as ligands that bind specific receptors. In the discovery and design of new drugs, it is helpful to know the specific receptor that the drug will bind, because then it is possible to determine the K_D value of its binding. This is one factor that can be taken into consideration when determining dosage levels. Of course, many drugs have side effects, and these are also dosage-dependent.

What happens when a ligand binds to a receptor? When we discussed small molecules binding to proteins in [Key Concept 3.2](#), we described how proteins often change shape when bound. This is exactly what happens to receptors. The change in the receptor's shape may expose a previously hidden group of amino acids on the protein that participate in a biochemical activity. This activity may be the binding of another molecule, such as another protein (e.g., a G protein, discussed below), or a substrate for an enzyme.

Instead of the ligand, other chemicals that resemble it can bind to the receptor. **Agonists** are

chemicals that set a receptor into signal transduction mode just as the ligand does. In contrast, inhibitors, or **antagonists**, bind to the receptor and “freeze” it in place, preventing the real ligand from binding, but do not set off signal transduction. Agonists and antagonists can be natural, or we can make them in the lab once we know the details of receptor–ligand binding.

agonist A chemical substance (e.g., a neurotransmitter) that elicits a specific response in a cell or tissue. (Contrast with antagonist.)

antagonist A biochemical substance (e.g., a drug) that blocks the normal action of another biochemical substance. (Contrast with agonist.)

Many substances that alter human behavior bind to specific receptors in the brain and prevent the binding of the receptors’ specific ligands. One example is caffeine, which is probably the world’s most widely consumed stimulant. In the brain, the nucleoside adenosine acts as a ligand that binds to a receptor on nerve cells, initiating a signal transduction pathway that reduces brain activity, especially feelings of active wakefulness. Because caffeine has a molecular structure similar to that of adenosine, it also binds to the adenosine receptor (**Figure 7.3B**). But in this case binding does not initiate a signal transduction pathway. Rather, it “ties up” the receptor, preventing adenosine binding and thereby allowing continued nerve cell activity and an active feeling.

Receptors can be classified by location and function

There are many kinds of chemical signals. Some ligands are hydrophobic (nonpolar) and can diffuse through membranes, whereas others cannot. Physical signals such as light also vary in their ability to penetrate cells and tissues. Correspondingly, a receptor can be classified by its location in the cell, which largely depends on the nature of its signal (**Figure 7.4**):

Figure 7.4 Two Locations for Receptors Receptors can be located inside the cell (in the cytoplasm or nucleus) or in the cell membrane.

Membrane receptors: Large or polar ligands cannot cross the lipid bilayer. Insulin, for example, is a protein hormone that cannot diffuse through the cell membrane; instead, it binds to a transmembrane receptor with an extracellular binding domain.

Intracellular receptors: Small or nonpolar ligands can diffuse across the nonpolar phospholipid bilayer of the cell membrane and enter the cell. The hormone estrogen, for example, is a lipid-soluble steroid (see in-text art p. 61) that can diffuse across the cell membrane; it binds to a receptor inside the cell. Light of certain wavelengths can penetrate the cells in a plant leaf quite easily, and many types of light receptors in plants are also intracellular.

In complex eukaryotes such as mammals and higher plants, there are three well-studied categories of cell membrane receptors that are grouped according to their functions: ion channels, protein kinase receptors, and G protein-coupled receptors.

ION CHANNELS

As you saw in [Key Concept 6.3](#), the cell membranes of many types of cells have gated **ion channels** that allow ions such as Na^+ , K^+ , Ca^{2+} , or Cl^- to enter or leave the cell. The gate-opening mechanism is an alteration in the three-dimensional shape of the channel protein upon interaction with a signal; thus these proteins function as ***receptors**. Each type of ion channel responds to a specific signal, including sensory stimuli such as light, sound, and electric charge differences across the cell membrane, as well as chemical ligands such as hormones and neurotransmitters.

ion channel An integral membrane protein that allows ions to diffuse across the membrane in which it is embedded.

The acetylcholine receptor, located in the cell membrane of skeletal muscle cells, is an example of an ion channel. This protein is a sodium channel that binds the ligand acetylcholine, which is a neurotransmitter—a chemical signal released from nerve cells ([Figure 7.5](#)). When two molecules of acetylcholine bind to the channel, it opens for about a thousandth of a second. That is enough time for Na^+ , which is more concentrated outside the cell than inside, to rush into the cell, moving in response to both concentration and electric potential gradients. The change in Na^+ concentration in the cell initiates a series of events that result in muscle contraction.

Figure 7.5 A Gated Ion Channel The acetylcholine receptor (AChR) is a ligand-gated ion channel for sodium ions. It is made up of five polypeptide subunits. When acetylcholine molecules (ACh) bind to two of the subunits, the gate opens and Na^+ flows into the cell. This channel helps regulate membrane polarity.

PROTEIN KINASE RECEPTORS

Some eukaryotic receptor proteins, called [protein kinases](#), catalyze the phosphorylation (adding phosphate) of themselves or other proteins, thus changing their shapes and therefore their functions.

protein kinase (kye' nase) An enzyme that catalyzes the addition of a phosphate group from ATP to a target protein.

Phosphorylation is a reaction that is especially important in biology. Of the estimated 21,000 genes that code for proteins in humans, more than 500 of them encode protein kinases. When you think of all the functions that make up a person, this is indeed an impressive number. The three amino acids that are phosphorylated are therefore worth knowing:

The receptor for insulin is an example of a protein kinase receptor. Insulin is a protein hormone made by the pancreas. Its receptor has two copies each of two different polypeptide subunits called α and β ([Figure 7.6](#)). When insulin binds to the receptor, the receptor becomes activated and is able to phosphorylate itself and certain cytoplasmic proteins that are appropriately called insulin-response substrates. These proteins then initiate many cellular responses, including the insertion of glucose transporters (see [Figure 6.12](#)) into the cell membrane.

Figure 7.6 A Protein Kinase Receptor The hormone insulin binds to a receptor on the outside surface of the cell and initiates a response.

G PROTEIN-COUPLED RECEPTORS

A third category of eukaryotic cell membrane receptors is the [G protein-coupled receptors](#), also referred to by the more impressive sounding name seven-transmembrane domain receptors. These receptors have many roles, including light detection in the mammalian retina (photoreceptors), detection of odors (olfactory receptors), and regulation of mood and behavior (such as mating in mammals and even single-celled yeasts). The receptors that bind the hormones oxytocin and vasopressin, which affect mating behavior in voles (see the opening story), are G protein-coupled receptors.

G protein-coupled receptors A class of receptors that change configuration upon ligand binding such that a G protein binding site is exposed on the cytoplasmic domain of the receptor, initiating a signal transduction pathway.

The seven-transmembrane domains of the receptor protein pass through the phospholipid bilayer and are separated by short loops that extend either outside or inside the cell. Ligand binding on the extracellular side of the receptor changes the shape of its cytoplasmic region, exposing a site that binds to a mobile membrane protein called a [G protein](#). The G protein is partially inserted into the lipid bilayer and partially exposed on the cytoplasmic surface of the membrane.

G protein A membrane protein involved in signal transduction; characterized by binding GDP or GTP.

Many G proteins have three polypeptide subunits and can bind three different types of

molecules ([Figure 7.7A](#)):

(A) The three units of a G protein-coupled receptor

(B) Activation of the G protein

(C) Activation of the effector protein

Figure 7.7 A G Protein-Coupled Receptor The G protein is an intermediary between the receptor and its effector.

Animation 7.1 A Signal Transduction Pathway www.Life11e.com/a7.1

- . The receptor
- . GDP and GTP (guanosine diphosphate and triphosphate, respectively; these are nucleoside phosphates like ADP and ATP)
- . An effector protein (see next paragraph)

When the G protein binds to an activated receptor protein, GDP is exchanged for GTP ([Figure 7.7B](#)). At the same time, the ligand is usually released from the extracellular side of the receptor. GTP binding causes a conformational change in the G protein. The GTP-bound subunit then separates from the rest of the G protein, diffusing in the plane of the phospholipid bilayer until it encounters an [effector protein](#) to which it can bind. An effector protein is just what its name implies: it causes an effect in the cell. The binding of the GTP-bearing G protein subunit activates the effector—which may be an enzyme or an ion channel—thereby causing changes in cell function ([Figure 7.7C](#)).

effector protein In cell signaling, a protein responsible for the cellular response to a signal transduction pathway.

After activation of the effector protein, the GTP bound to the G protein is hydrolyzed to GDP. The now inactive G protein subunit separates from the effector protein and diffuses in the membrane to collide with and bind to the other two G protein subunits. When the three components of the G protein are reassembled, the protein is capable of binding again to an activated receptor. After binding, the activated receptor exchanges the GDP on the G protein for a GTP, and the cycle begins again.

Intracellular receptors are located in the cytoplasm or the nucleus

Intracellular receptors are located inside the cell and respond to physical signals such as light (e.g., some photoreceptors in plants) or chemical signals that can diffuse across the cell membrane (e.g., steroid hormones in animals). Many intracellular receptors are transcription factors. Some are located in the cytoplasm until they are activated; after binding their ligands, these transcription factors move to the nucleus where they bind to DNA and alter the expression of specific genes. A typical example is the receptor for the steroid hormone cortisol. This receptor is normally bound to a chaperone protein that blocks it from entering the nucleus. Binding of the hormone causes the receptor to change its shape so that the chaperone is released (**Figure 7.8**). This release allows the receptor to enter the nucleus, where it affects DNA transcription. Another group of intracellular receptors is always located in the nucleus, and their ligands must enter the nucleus before binding.

intracellular receptor A receptor that binds its ligand inside the cell. An example is the estrogen receptor in mammals.

Figure 7.8 An Intracellular Receptor The receptor for cortisol is in the cytoplasm, bound to a chaperone protein that is released when cortisol binds to the receptor.

7.2 recap

Receptors are proteins that bind, or are changed by, specific ligands or physical signals.

The changed receptor initiates a response in the cell. These receptors are located in the cell membrane or inside the cell.

learning outcomes

You should be able to:

- Explain how and why different cells respond to different chemical signals.
 - Using equations, describe the chemical kinetics of receptor–ligand interactions.
 - Analyze dissociation constants as a measure of binding affinity.
 - Compare and contrast cell membrane receptors and intracellular receptors.
-

1. What is the dissociation constant K_D , and what does it tell us about the likelihood that a signal will produce a cellular response?
 2. What is the chemical nature and importance of specificity in the binding of a receptor to its particular ligand?
 3. What are the differences between receptors located in the cytoplasm and those at the cell membrane?
-

Now that we have discussed signals and receptors, let's examine the characteristics of the molecules (transducers) that mediate the cellular response.

* **connect the concepts** Ion channels are key to the functioning of the nervous system. An example is the connection between nerve and muscle described in [Key Concepts 44.3](#) and [47.1](#).

7.3 The Response to a Signal Spreads through the Cell

As you have seen, there are different kinds of signals and receptors. Not surprisingly, the ways that signals are transduced, and the resulting cellular responses, also vary. Some signal transduction pathways are quite simple and direct, whereas others involve multiple steps. As we mentioned in [Key Concept 7.1](#), signal transduction pathways can involve enzymes and transcription factors. In addition, [second messengers](#) can diffuse throughout the cytoplasm and mediate further steps in pathways.

second messenger A compound, such as cAMP, that is released within a target cell after a hormone (the first messenger) has bound to a surface receptor on a cell; the second messenger triggers further reactions within the cell.

focus your learning

A signal transduction cascade transmits and amplifies a signal inside a cell.

Second-messenger molecules can transmit and amplify signals within a cell.

Signal transduction is regulated in a cell by various mechanisms.

In many cases, a signal can initiate a cascade (chain) of events, in which proteins interact with other proteins, which interact with still other proteins until the final responses are achieved. Through such a cascade, an initial signal can be both amplified and distributed to cause several different responses in the target cell. In this section we will examine the kinds of molecules that transduce signals and look at several different signal transduction pathways.

The cell amplifies its response to ligand binding

Scientists worked out the signal transduction pathway for one growth factor by studying a cell that went wrong. Many human bladder cancers contain an abnormal form of a protein called ras (so named because a similar protein was previously isolated from a rat sarcoma tumor). Investigations of these bladder cancers showed that ras was a G protein. Recall that G proteins function as switches with “on” and “off” states. In the “off” state, G protein is bound to GDP, whereas in the “on” state the protein becomes bound to GTP. The abnormal form of the ras protein under study was always active because it was permanently bound to GTP and thus caused continuous cell division ([Figure 7.9](#)).

(A) Ras function in a normal cell

(B) Abnormal ras function in a cancer cell

Figure 7.9 Signal Transduction and Cancer (A) Ras is a G protein that regulates cell division. (B) In some tumors, the ras protein is permanently active, resulting in uncontrolled cell division.

Animation 7.2 **Signal Transduction and Cancer** www.Life11e.com/a7.2

Other cancer cells have abnormalities in different parts of the same signal transduction pathway. By comparing the defects in abnormal cells with the normal signaling process in non-cancer cells, biologists worked out the entire signaling pathway (**Focus: Key Figure 7.10**). Recall from [Key Concept 7.2](#) that G protein mediates a response after activation by the protein kinase receptor. In [Figure 7.10](#), the activated G protein ras initiates a series of additional events comprising a signal transduction pathway known as a **protein kinase cascade**, where one protein kinase activates the next, and so on. Such cascades are key to the regulation of many cellular activities. Protein kinase cascades are useful signal transducers for four reasons:

Figure 7.10 A Protein Kinase Cascade In a protein kinase cascade, a series of proteins are sequentially activated.

Q: Sorafenib is a drug that was designed to inhibit raf, which is very active in kidney cancer. How does this drug work on the protein kinase cascade?

protein kinase cascade A series of reactions in response to a molecular signal, in which a series of protein kinases activate one another in sequence, amplifying the signal at each step.

- At each step in the cascade of events, the signal is *amplified*, because each newly activated protein kinase is an enzyme that can catalyze the phosphorylation of many target proteins (see [Figure 7.10](#), steps 5 and 6).
- The information from a signal that originally arrived at the cell membrane is *communicated* to the nucleus, where the expression of multiple genes is often modified.
- The multitude of steps provides some *specificity* to the process.
- Different target proteins at each step in the cascade can provide *variation* in the response.

Second messengers can amplify signals between receptors and target molecules

Often there is a small molecule intermediary between the activated receptor and the cascade of events that ensues. Earl Sutherland and his colleagues at Case Western Reserve University discovered one such molecule when they were investigating the activation of the liver enzyme glycogen phosphorylase by the hormone epinephrine. The hormone is released when an animal

faces life-threatening conditions and needs energy fast for the fight-or-flight response (see [Figure 40.3](#)). Glycogen phosphorylase catalyzes the breakdown of glycogen stored in the liver so that the resulting glucose molecules can be released to the blood. The enzyme is present in the liver cell cytoplasm but is inactive unless the liver cells are exposed to epinephrine:

The researchers found that epinephrine could activate glycogen phosphorylase in liver cells that had been broken open, but only if the entire cell contents, including cell membrane fragments, were present. Under these conditions epinephrine was bound to the cell membrane fragments (the location of its receptor), but the active phosphorylase was present in the solution. Adding epinephrine to just cytoplasm with inactive phosphorylase did not result in activation. The researchers hypothesized that there must be a “second messenger” that transmits the epinephrine signal (epinephrine being the “first messenger”). The experiments confirmed the existence of a second messenger, later identified as [cyclic AMP \(cAMP\)](#), which is produced from ATP by the enzyme adenylyl cyclase ([Figure 7.11](#)). Adenylyl cyclase is activated via a G protein-coupled epinephrine receptor (see the first steps in [Figure 7.15](#)).

cyclic AMP See cAMP.

cAMP (cyclic AMP) A compound formed from ATP that acts as a second messenger.

Figure 7.11 The Formation of Cyclic AMP The formation of cAMP from ATP is

catalyzed by adenylyl cyclase, an enzyme that is activated by G proteins.

In contrast to the specificity of receptor binding, second messengers such as cAMP allow a cell to respond to a single event at the cell membrane with many events inside the cell. Thus second messengers serve to rapidly amplify and distribute the signal—for example, binding of a single epinephrine molecule leads to the production of many molecules of cAMP, which then activate many enzyme targets by binding to them noncovalently. In the case of epinephrine and the liver cell, glycogen phosphorylase is just one of several enzymes that are activated.

Second messengers are often involved in crosstalk between different signaling pathways. Activation of the epinephrine receptor is not the only way for a cell to produce cAMP; and as noted, there are multiple targets of cAMP in the cell, and these targets are parts of other pathways.

Several other classes of second messengers have since been identified, including lipid-derived second messengers, calcium ions, and nitric oxide.

LIPID-DERIVED SECOND MESSENGERS

In addition to their role as structural components of the cell membrane, phospholipids are also involved in signal transduction. When certain phospholipids are hydrolyzed into their component parts by enzymes called phospholipases, second messengers are formed.

The best-studied examples of lipid-derived second messengers come from hydrolysis of the phospholipid **phosphatidyl inositol-bisphosphate (PIP₂)**. Like all phospholipids, PIP₂ has a hydrophobic portion embedded in the cell membrane: two fatty acid tails attached to a molecule of glycerol, which together form **diacylglycerol**, or **DAG**. The hydrophilic portion of PIP₂ is **inositol trisphosphate**, or **IP₃**, which projects into the cytoplasm.

phosphatidyl inositol-bisphosphate (PIP₂) A phospholipid in the cell membrane that is involved in cell signaling after a ligand binds to a nearby receptor.

DAG See diacylglycerol.

inositol trisphosphate (IP₃) An intracellular second messenger derived from membrane phospholipids.

As with cAMP, the receptors involved in this second-messenger system are often G protein-coupled receptors. A G protein subunit is activated by the receptor, then diffuses within the cell membrane and activates phospholipase C, an enzyme that is also located in the membrane. This enzyme cleaves off the IP₃ from PIP₂, leaving the diacylglycerol (DAG) in the phospholipid bilayer:

IP₃ and DAG are both second messengers; they have different modes of action that build on each other to activate protein kinase C (PKC). PKC refers to a family of protein kinases that can

phosphorylate a wide variety of target proteins, leading to a multiplicity of cellular responses that vary depending on the tissue or cell type.

CALCIUM IONS

Calcium ions (Ca^{2+}) are scarce inside most cells, which have cytosolic Ca^{2+} concentrations of only about 0.1 micromolar (μM). Ca^{2+} concentrations outside cells and within the endoplasmic reticulum (ER) are usually much higher. Active transport proteins in the cell and ER membranes maintain this concentration difference by pumping Ca^{2+} out of the cytosol. In contrast to cAMP and the lipid-derived second messengers, Ca^{2+} cannot be synthesized to increase the intracellular Ca^{2+} concentration. Instead, Ca^{2+} ion levels are regulated via the opening and closing of ion channels and the action of membrane pumps.

Many signals can cause calcium channels to open, including IP_3 . The entry of a sperm into an egg is a very important signal that causes a massive opening of calcium channels, resulting in numerous and dramatic changes that prepare the now-fertilized egg for cell division and development ([Figure 7.12](#)). Whatever the initial signal that causes calcium channels to open, their opening results in a dramatic increase in cytosolic Ca^{2+} concentration, which can increase up to 100-fold within a fraction of a second. This increase activates PKC. In addition, Ca^{2+} controls other ion channels and stimulates secretion by exocytosis in many cell types.

Figure 7.12 Calcium Ions as Second Messengers The concentration of Ca^{2+} can be measured using a dye that fluoresces when it binds the ion. Here, fertilization in a sea star egg causes a rush of Ca^{2+} from the environment into the cytoplasm. Areas of high Ca^{2+} concentration are indicated by the red color, and the events are photographed at 5-second intervals. Calcium signaling occurs in virtually all animal groups and triggers cell division in fertilized eggs, initiating the development of new individuals.

NITRIC OXIDE

Most signaling molecules and second messengers are solutes that remain dissolved in either the aqueous or hydrophobic components of cells. It was a great surprise to find that a gas could also be active in signal transduction. Nitric oxide (NO) is a second messenger in the signal transduction pathway between the neurotransmitter acetylcholine (see [Key Concept 7.2](#)) and the

relaxation of smooth muscles lining blood vessels, which allows more blood flow ([Figure 7.13](#)). In the body, NO is made from the amino acid arginine by the enzyme NO synthase. When the acetylcholine receptor on the surface of an endothelial cell is activated, IP₃ is released from the membrane (via the pathway shown in [Figure 7.13](#)), causing a calcium channel in the ER membrane to open and a subsequent increase in cytosolic Ca²⁺. The Ca²⁺ then activates NO synthase to produce NO. NO is chemically very unstable, readily reacting with oxygen gas as well as other small molecules. Although NO diffuses readily, it does not get far. Conveniently, the endothelial cells are close to the underlying smooth muscle cells, where NO activates an enzyme called guanylyl cyclase (a close relative of adenylyl cyclase). This enzyme catalyzes the formation of cyclic GMP (cGMP): yet another second messenger that contributes to the relaxation of muscle cells.

Figure 7.13 Nitric Oxide in Signal Transduction Nitric oxide (NO) is an unstable

gas, which nevertheless serves as a mediator between a signal, acetylcholine (ACh), and its effect: the relaxation of smooth muscles.

The discovery of NO as a participant in signal transduction explained the action of nitroglycerin, a drug that has been used for more than a century to treat angina, the chest pain caused by insufficient blood flow to the heart. Nitroglycerin releases NO, which results in relaxation of the blood vessels and increased blood flow. The drug sildenafil (Viagra) was developed to treat angina via the NO signal transduction pathway but was only modestly useful for that purpose. However, men taking it reported more pronounced penile erections. During sexual stimulation, NO acts as a signal, causing an increase in cGMP and a subsequent relaxation of the smooth muscles surrounding the arteries in the corpus cavernosum of the penis. As a result of this signal, the penis fills with blood, producing an erection. Sildenafil acts by inhibiting an enzyme (a phosphodiesterase) that breaks down cGMP—resulting in more cGMP and better erections.

Signal transduction is highly regulated

Cells can regulate the activity of a molecule involved in signal transduction. The concentration of NO, which breaks down quickly, can be regulated only by how much of it is made. By contrast, membrane pumps and ion channels regulate the cytosolic concentration of Ca^{2+} , as you have seen. To regulate protein kinase cascades, G proteins, and cAMP, there are enzymes that inactivate the activated transducer ([Figure 7.14](#)).

(A) Phosphatase inactivates a protein kinase

(B) GTPase inactivates a G protein

(C) Phosphodiesterase Inactivates cAMP

Figure 7.14 Regulation of Signal Transduction Some signals lead to the production of active transducers such as **(A)** protein kinases, **(B)** G proteins, and **(C)** cAMP. Other enzymes (shown in red) inactivate or remove these transducers.

The balance between the activities of enzymes that activate and inactivate transducers determines the ultimate cellular response to a signal. Cells can alter this balance in several ways:

Synthesis or breakdown of the enzymes. For example, synthesis of adenylyl cyclase (which synthesizes cAMP) and breakdown of phosphodiesterase (which breaks down cAMP) would tilt the balance in favor of more cAMP in the cell.

Activation or inhibition of the enzymes by other molecules. An example is the inhibition of phosphodiesterase by sildenafil.

Because cell signaling is so important in diseases such as cancer, a search is under way for new drugs that can modulate the activities of enzymes that participate in signal transduction pathways.

7.3 recap

Signal transduction is the series of steps between the binding of a signal to a receptor and the ultimate cellular response. A protein kinase cascade amplifies a signal through a series of protein phosphorylation reactions. In many cases, a second messenger amplifies and distributes the downstream effects of the signal. The activity of transducer molecules is regulated.

learning outcomes

You should be able to:

- Describe how a protein cascade amplifies a signal.
- Explain how the same second-messenger molecule can be used in many different signal transduction pathways.
- Explain how signal transduction pathways are regulated in a cell.

1. How can an activated G protein such as ras amplify a response to ligand binding?
2. Cyclic AMP is a second messenger in many different responses. How can the same messenger act in different ways in different cells?
3. How are signal transduction cascades regulated?

You have seen how the binding of a signal to its receptor initiates the response of a cell to the signal, and how signal transduction pathways amplify the signal and distribute its effects to numerous targets in the cell. In the next section we will look at the third step in the signal transduction process, the actual effects of the signal on cell function.

7.4 Cells Change in Response to Signals in Several Ways

The effects of a signal on cell function take three primary forms: the opening of ion channels, changes in the activities of enzymes, or differential gene expression. These events set the cell on a path for further and sometimes dramatic changes in form and function.

focus your learning

A cell can respond to signals by opening or closing ion channels.

A cell can respond to signals by altering gene transcription.

Ion channels respond to signals by opening or closing

You have seen that ion channels can function as receptors in cell signaling (see [Figure 7.5](#)). In [Chapters 44](#) and [45](#), you will learn how signaling affects ion channels in the central nervous system and in senses, where stimulation of a receptor by light, sound, or touch can lead to opening of an ion channel. A different type of ion channel response lies within some cells. For example, signal transduction using the IP₃–DAG pathway can result in the opening of Ca²⁺ channels in the ER membrane.

Oxytocin, which we described in the opening of this chapter, combines the two ion channel responses. Oxytocin binds to a G protein-coupled receptor (see [Figure 7.7](#)), which is expressed in brain tissue as well as muscles involved in birth and lactation. Activation of the receptor results in signal transduction through the IP₃–DAG pathway, releasing Ca²⁺ into the cytoplasm via ion channels. In the brain, the effect of Ca²⁺ is to indirectly stimulate nerve cell activity by the opening of ion channels for Na⁺, as you will learn in [Chapter 44](#). To summarize:

Oxytocin → Receptor → G protein activation → IP₃ signal transduction → Ca²⁺ channel opening
→ Na⁺ channel opening

You saw in the opening of this chapter that the behavioral effect of oxytocin in voles involves bonding between them. Does this also happen in people? Neuroscientist Paul Zak at the Center for Neuroeconomics Studies thinks so. He has done experiments with human volunteers and shown that oxytocin signaling is important in trusting behavior (**Investigating Life: Is Oxytocin a “Trust” Signal in Humans?**). Recently, it was shown that people who have an inherited defect in the oxytocin receptor act in some ways like the montane voles that lack oxytocin receptors: they are less trusting.

Enzyme activities change in response to signals

Enzymes are often modified during signal transduction—either covalently or noncovalently. You have seen examples of both types of protein modifications earlier in this chapter. For example, addition of a phosphate group to an enzyme by a protein kinase is a covalent change; cAMP binding is noncovalent. Both types of modifications change the enzyme’s shape, activating or inhibiting its function. In the case of activation, the shape change exposes a previously inaccessible active site, and the target enzyme goes on to perform a new cellular role.

The G protein-mediated protein kinase cascade that is stimulated by epinephrine in liver cells results in the activation by cAMP of a key signaling molecule, protein kinase A. In turn, protein kinase A phosphorylates two other *enzymes, with opposite effects:

- . *Inhibition*: Glycogen synthase, which catalyzes the joining of glucose molecules to synthesize the energy-storing molecule glycogen, is inactivated when a phosphate group is added to it by protein kinase A. Thus the epinephrine signal *prevents glucose from being stored* in the form of glycogen ([Figure 7.15](#), **step 1**).

Figure 7.15 A Cascade of Reactions Leads to Altered Enzyme Activity Liver cells respond to epinephrine by activating G proteins, which in turn activate the synthesis of the second messenger cAMP. Cyclic AMP initiates a protein kinase cascade, greatly amplifying the epinephrine signal, as indicated by the bold, black numbers. The cascade both inhibits the conversion of glucose to glycogen and stimulates the release of previously stored glucose.

. **Activation:** Phosphorylase kinase is activated when a phosphate group is added to it. It is part of a protein kinase cascade that ultimately leads to the activation of glycogen phosphorylase, another key enzyme in glucose metabolism. This enzyme results in the *liberation of glucose molecules* from glycogen ([Figure 7.15](#), **steps 2 and 3**).

The amplification of the signal in this pathway is impressive; as detailed in [Figure 7.15](#), each molecule of epinephrine that arrives at the cell membrane ultimately results in the release of 10,000 molecules of glucose into the bloodstream:

- 1** molecule of epinephrine bound to the membrane leads to
- 20** molecules of cAMP, which activate
- 20** molecules of protein kinase A, which activate
- 100** molecules of phosphorylase kinase, which activate
- 1,000** molecules of glycogen phosphorylase, which produce
- 10,000** molecules of glucose 1-phosphate, which produce
- 10,000** molecules of blood glucose

investigatinglife Signal in Humans?

Is Oxytocin a “Trust”

experiment

Original Paper: Zak, P., R. Kurzban and W. T. Matzner. 2005. Oxytocin is associated with human trustworthiness. *Hormones and Behavior* 48: 522–527.

Cell signaling in the brain leads to changes in behavior. This experiment investigates whether the peptide oxytocin correlates with the development of trust between humans.

HYPOTHESIS▶ The signal oxytocin is involved in trust between humans.

METHOD

- 156 people given \$10 to participate.

- People randomly assigned to pairs who do not meet.

- Donor and recipient are told that donor can give up to \$10 to the recipient, which will be tripled in recipient's account, and that the recipient can reward the donor.

- Establish Trust:** Donor hopes recipient will reward donor out of the tripled account more than donor gave. Trustworthiness is seen when recipient feels good about donor's generosity and gives back to donor.

- Establish a Control Group:** In the control group donors are told at random exactly what to give, and recipients are aware of this. So there was no donor intention to be generous.

- Measure oxytocin levels in blood of donors in both experimental and control groups immediately after the donor decides what to give the recipient.

RESULTS

	Experimental (donor intent)	Control (no intent)
Amount given by donor	\$5.52	\$5.63
Amount returned by recipient	\$6.96	\$3.53
Oxytocin level in recipient (pg/ml)	278	198

CONCLUSIONS

- People (recipients) who trust another person (donor, experimental) will be more trustworthy than people who do not have that feeling.
- Oxytocin levels are higher in people who are trustworthy.

work with the data

Original Paper: Kosfeld, M., M. Heinrichs, P. Zak, U. Fischbaker and E. Fehr. 2005. Oxytocin increases trust in humans. *Nature* 435: 673–676.

Paul Zak used an economics experiment to investigate trust and found that when people felt that a stranger had trusted them with money, the recipients not only reciprocated by giving the donor some money back, but also had elevated levels of the intercellular signaling molecule oxytocin. As in many experiments, although these data were suggestive of a relationship, correlation does not necessarily mean causation. So Zak and his colleagues tried a direct experiment in which subjects were given oxytocin before the experiment, to determine if oxytocin induces greater trust.

QUESTIONS

- In the experiment, donors were divided into control and experimental groups and paired with recipients. All donors were given 12 money units and asked to donate to a paired recipient, whom they did not know or see. Donors knew that whatever amount they donated would be tripled in the recipient's account (up to 36 units) and trusted that the recipient would generously give some money back to the donor. The experimental donor group was given nasal spray containing oxytocin just before the experiment; the control donor group received a nasal spray without oxytocin. The table shows the results.

	Average number of units (SD) sent to recipient
Experimental group (with oxytocin spray)	9.6 (2.8)
Control (no oxytocin spray)	8.1 (3.1)

What can you conclude from these data about oxytocin and trust in the donors? What statistical test would you use to show that the two averages are significantly different?

- The experiment described in Question 1 was repeated, but this time both donor groups were told exactly how much to give the recipient. The results are shown in the table.

	Average number of units (SD) sent to recipient
Experimental group (with oxytocin spray)	7.5 (3.3)
Control (no oxytocin spray)	7.5 (3.4)

What can you conclude about the effect of oxytocin in this case, and what does it indicate about the trust relationship?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Signals can initiate DNA transcription

You learned in [Key Concept 4.1](#) that the genetic material, DNA, is transcribed into RNA, which is then translated into a protein whose amino acid sequence is specified by the original DNA sequence. Proteins are important in all cellular functions, so a key way to regulate specific functions in a cell is to regulate which proteins are made, and therefore which DNA sequences are transcribed.

***Signal transduction** plays an important role in determining which DNA sequences are transcribed. Common targets of signal transduction are proteins called transcription factors, which bind to specific DNA sequences in the cell nucleus and activate or inactivate transcription of the adjacent DNA regions. For example, the ras signaling pathway (see [Figure 7.10](#)) ends in the nucleus. The final protein kinase in the ras signaling cascade, MAPK (mitogen-activated protein kinase; a mitogen is a type of signal that stimulates cell division), enters the nucleus and phosphorylates a protein that stimulates the expression of several genes involved in cell

proliferation.

7.4 recap

Cells respond to signal transduction by opening membrane channels, activating or inactivating enzymes, and stimulating or inhibiting gene transcription.

learning outcomes

You should be able to:

- Describe the signal transduction pathway stimulated by oxytocin.
- Compare various mechanisms that cells use to respond to signals.

1. How does oxytocin signaling involve several signaling pathways?
2. Which method(s) of cell response to signaling are rapid and which are slower? Explain.

We have described how signals from a cell's environment can influence the cell. But the environment of a cell in a multicellular organism is more than the extracellular medium—it includes neighboring cells as well. In the next section we'll see how specialized junctions between cells allow them to pass signals from one to another.

*** [connect the concepts](#)** Enzyme regulation determines the rate of chemical transformations in cells, and thus cell functions. See [Key Concept 8.5](#).

*** [connect the concepts](#)** In this chapter you've learned about signaling pathways that occur in animal cells. Signal transduction pathways play equally important roles in other organisms, including plants, as we will explore extensively in [Chapters 36](#) and [38](#).

7.5 Adjacent Cells in a Multicellular Organism Can Communicate Directly

The hallmark of multicellular organisms is their ability to have specialized functions in subsets of cells within their bodies. How do these cells communicate with one another so that they can work together for the good of the entire organism? As you learned in [Key Concept 7.1](#), some intercellular signals travel through the circulatory system to reach their target cells. But cells also have more direct ways of communicating. Cells that are packed together within a tissue can communicate directly with their neighbors via specialized intercellular junctions: gap junctions in animals (see [Figure 6.7](#)) and plasmodesmata in plants (see [Figure 5.7](#)).

focus your learning

Animal cells can communicate directly with other cells via gap junctions.

Development of intercellular communication was a key step in the evolution of multicellularity.

How do animal cells directly communicate?

Gap junctions are channels between adjacent cells that occur in many animals, occupying up to 25 percent of the area of the cell membrane ([Figure 7.16A](#)). Gap junctions traverse the narrow space between the cell membranes of two adjacent cells (the “gap”) by means of channel structures called **connexons**. The walls of a connexon are composed of six subunits of the integral membrane protein connexin. In adjacent cells, two connexons come together to form a gap junction that links the cytoplasms of the two cells. There may be hundreds of these channels between a cell and its neighbors. The channel pores are about 1.5 nanometers (nm) in diameter—too narrow for the passage of large molecules but adequate for passage of small molecules and ions.

gap junction A 2.7-nanometer gap between cell membranes of two animal cells, spanned by protein channels. Gap junctions allow chemical substances or electrical signals to pass from cell to cell.

connexon In a gap junction, a protein channel linking adjacent animal cells.

(A) Gap junctions in animal cells

(B) Plasmodesmata in plant cells

Figure 7.16 Communicating Junctions (A) An animal cell may contain hundreds of gap junctions connecting it to neighboring cells. The pores of gap junctions allow small molecules to pass from cell to cell, ensuring similar concentrations of important signaling molecules in adjacent cells so that the cells can coordinate their activities. (B) Plasmodesmata connect plant cells. The desmotubule, derived from the smooth endoplasmic reticulum, fills up most of the space inside a plasmodesma, leaving a tiny gap through which small metabolites and ions can pass.

Here is an example of gap junctions at work: In the lens of the mammalian eye, only the cells at the periphery are close enough to the blood supply for adequate diffusion of nutrients and wastes. But because lens cells are connected by large numbers of gap junctions, material can diffuse between them rapidly and efficiently. Hormones and second messengers can move

through gap junctions. Sometimes just a few cells in a tissue have the receptor for a particular signal; in such cases, gap junctions allow a coordinated response to the signal by all the cells in the tissue.

Plant cells communicate through plasmodesmata

Instead of gap junctions, plants have **plasmodesmata** (singular *plasmodesma*), which are membrane-lined tunnels that traverse the thick cell walls separating plant cells from one another. A typical plant cell has several thousand plasmodesmata. Plasmodesmata differ from gap junctions in one fundamental way: unlike gap junctions, in which the wall of the channel is made of integral membrane proteins from the adjacent cell membranes, plasmodesmata are lined by the fused cell membranes themselves.

plasmodesmata (singular: plasmodesma) [Gk. *plassein*: to mold + *desmos*: band]
Cytoplasmic strands connecting two adjacent plant cells.

The diameter of a plasmodesma is about 6 nm, far larger than a gap junction channel. But the actual space available for diffusion is about the same—1.5 nm. Examination of the interior of the plasmodesma by transmission electron microscopy reveals that a tubule called the **desmotubule**, apparently derived from the endoplasmic reticulum, fills up most of the opening of the plasmodesma (**Figure 7.16B**). Typically, only small metabolites and ions can move between plant cells.

desmotubule A membrane extension connecting the endoplasmic reticulum of two plant cells that traverses the plasmodesma.

Plasmodesmata are vital in plants because their circulatory transport system, the vascular system, lacks the tiny vessels (capillaries) that many animals have for bringing gases and nutrients to every cell. For instance, simple diffusion from plant cell to cell across cell membranes is inadequate to account for the movement of a plant hormone from the site of production to the site of action. Instead, plants rely on more rapid diffusion through plasmodesmata to ensure that all cells of a tissue respond to a signal at the same time. There are cases in which larger molecules or particles can pass between cells via plasmodesmata. For example, some viruses can move through plasmodesmata by using “movement proteins” to assist their passage.

Modern organisms provide clues about the evolution of cell–cell interactions and multicellularity

Multicellular organisms can indeed be multicellular—a human has about 60 trillion eukaryotic cells and many more prokaryotic ones. But it’s not just cells that make up a human or a rose plant—it is groups of cells specialized into tissues and then groups of tissues in organs (e.g., the nerve cells in the brain or the petals in a flower) that have specific roles. As you will learn in **Chapter 19**, the embryonic development of tissues and organs takes place in several steps:

- Migration of cells to form a group
- Organization of cells in the cluster
- Specialization of cells into tissues
- Connections between cells

Even though single-celled organisms continue to be highly successful on Earth, over time

complex multicellular organisms evolved, along with their division of biological labor among specialized cells. The transition from single-celled to multicellular life took a long time. Indeed, while there is evidence that single-celled organisms arose about 500 million to a billion years after the formation of Earth (see [Chapter 4](#)), the first evidence of true multicellular organisms dates from more than a billion years later. Multicellularity probably arose several times.

Studying the evolutionary origin of multicellularity is a challenge because it happened so long ago. The closest unicellular relatives of most modern animals and plants probably existed hundreds of millions of years ago. The transition from single-celled to multicellular organisms may have occurred in several steps:

- Aggregation of cells into a cluster

- Intercellular communication within the cluster

- Specialization of some cells within the cluster

- Organization of specialized cells into groups (tissues)

Does this list look familiar? (See above for the origin of organs in the embryo.)

A key event would have been the evolution of intercellular communication, which is necessary to coordinate the activities of different cells within a multicellular organism.

We can visualize how the evolution of multicellularity might have occurred by looking at the “Volvocine line” of aquatic green algae (Chlorophyta). These plants range from single cells to complex multicellular organisms with differentiated cell clusters ([Figure 7.17](#)). Included in this range are a single-celled organism (*Chlamydomonas*); an organism that occurs in small cell clusters (*Gonium*); species with larger cell clusters (*Pandorina* and *Eudorina*); a colony of somatic and reproductive cells (*Pleodorina*); and a larger, 1,000-celled alga with somatic and reproductive cells organized into separate tissues (*Volvox*).

Figure 7.17 Multicellularity The evolution of intercellular interactions in a multicellular organism can be inferred from these green algae.

Q: Why was the evolution of direct communication important for tissue formation?

Chlamydomonas is the single-celled member of this group. It has two cellular phases: a swimming phase, when the cells have flagella and move about, and a non-swimming phase, when the flagella are reabsorbed (disaggregated) and the cell undergoes cell division (reproduction). Compare this with *Volvox*: most of the cells of this multicellular, spherical organism are on the surface; the beating of their flagella gives the organism a rolling motion as it swims toward light, where it can perform photosynthesis. But some *Volvox* cells are larger and located inside the sphere. These cells are specialized for reproduction: they lose their flagella and then divide to form offspring.

 Media Clip 7.1 **Social Amoebas Aggregate on Cue** www.Life11e.com/mc7.1

The separation of somatic and reproductive functions in *Volvox* is possible because of a key intercellular signaling mechanism that coordinates the activities of the separate tissues within the organism. *Volvox* has a gene whose protein product is produced by the outer, motile cells and travels to the reproductive cells, causing them to lose their flagella and divide. This gene is not active in species such as *Gonium* and *Pandorina*, which show cell aggregation but no cell specialization.

Cells can communicate with their neighbors through specialized cell junctions. In animals, these structures are gap junctions; in plants, they are plasmodesmata. The evolution of intercellular communication and tissue formation can be inferred from existing organisms, such as certain related green algae.

learning outcomes

- Explain the biological advantages of gap junctions in animals.
 - Design investigations to answer questions about intercellular communication.
-
1. List the characteristics of direct communication by cell junctions and chemical signaling between cells. What are the advantages of direct communication over chemical signaling?
 2. How does the Volvocine line of green algae show possible steps in the evolution of cell communication and tissue formation?
 3. The tiny invertebrate *Hydra* has an apical region with tentacles and a long, slender body. *Hydra* can reproduce asexually when cells on the body wall differentiate and form a bud, which then breaks off as a new organism. Buds form only at certain distances from the apex, leading to the idea that the apex releases a signal molecule that diffuses down the body and, at high concentrations (i.e., near the apex), inhibits bud formation. *Hydra* lacks a circulatory system, so this inhibitor must diffuse from cell to cell. If you have an antibody that binds to connexons and plugs up the gap junctions, how would you test the hypothesis that *Hydra*'s inhibitory factor passes through these junctions?

QA Is oxytocin the “trust” signal in humans?

Paul Zak's experiments showing the involvement of oxytocin in the trust involved in money transfers between people opened up a new field of study called neuroeconomics. In 1759 the philosopher Adam Smith wrote that social and economic interactions between people are driven by what he called “fellow feeling.” Now, 250 years later, the oxytocin studies validate this and have put it into the language of cell signaling. What other things besides economic generosity release oxytocin? Zak and others have shown that many pleasant activities, even massage and hugs, release oxytocin and induce positive behaviors as a result. Oxytocin is released during sexual activity in humans, and the release results in bonding behaviors just as it does in voles. Of course, oxytocin is now available for purchase. An ad proclaims “We 100% guarantee that Oxytocin Spray will enrich your social life or your money back.”

Future directions

In this chapter you have seen how a natural substance such as caffeine acts on receptors to alter cell function. As signal transduction pathways have been described for important processes such as the regulation of cell division, it has become possible to perturb intermediate steps in the pathway between signal and cell effects. In the signaling that stimulates cells to reproduce, two important steps are the focus of intense interest. One is at the cell membrane and involves the ras GTPase that converts GTP bound to ras to GDP that can be inactive in cancer cells (see [Figure 7.9](#)). Drugs that target this GTPase make it more active, so there is less active ras in the cell and the signal transduction pathway for cell division does not get under way. Another area of intense interest is an intermediate step in the phospholipase C pathway (see [Figure 7.14](#)) that involves the protein kinase mTOR. Several drugs that target mTOR inactivate it, resulting in less cell division in tumor cells and cells involved in inflammation.

7.1 Signals and Signaling Affect Cell Function

- Cells receive many signals from the environment and from other cells. Chemical signals are often at very low concentrations. **Autocrine** signals affect the cells that make them; **juxtacrine** signals affect adjacent cells; **paracrine** signals diffuse to and affect nearby cells; and **hormones** are carried through the circulatory systems of animals or the vascular systems of plants. **Review Figure 7.1, Activity 7.1**

autocrine A chemical signal that binds to and affects the cell that makes it. (Contrast with paracrine.)

juxtacrine A mode of cell communication where the cell producing a signal is in contact with the cell bearing the receptor for that signal.

paracrine [Gk. *para*: near] Pertaining to a chemical signal, such as a hormone, that acts locally, near the site of its secretion. (Contrast with autocrine.)

hormone (hore' mone) [Gk. *hormon*: to excite, stimulate] A chemical signal produced in minute amounts at one site in a multicellular organism and transported to another site where it acts on target cells.

- A **signal transduction pathway** involves the interaction of a signal molecule with a receptor; the transduction of the signal via a series of steps within the cell; and effects on the function of the cell. **Review Figure 7.2**

signal transduction pathway The series of biochemical steps whereby a stimulus to a cell (such as a hormone or neurotransmitter binding to a receptor) is translated into a response of the cell.

- Signal transduction pathways involve regulation of enzymes and transcription factors. A great deal of **crosstalk** occurs between pathways.

crosstalk Interactions between different signal transduction pathways.

7.2 Receptors Bind Signals to Initiate a Cellular Response

- Cells respond to signals only if they have specific **receptor** proteins that can recognize those signals.

receptor See receptor protein, sensor.

- Binding of a signal **ligand** to its receptor obeys the chemical law of mass action. A key measurement of the strength of binding is the **dissociation constant (K_D)**.

ligand (lig' and) Any molecule that binds to a receptor site of another (usually larger) molecule.

dissociation constant (K_D) A type of equilibrium constant measuring the tendency of a two substances that are bound together to separate into the two smaller components. In cell signaling, the two substances are a ligand and receptor.

- Depending on the nature of its signal or ligand, a receptor may be located in the cell membrane or inside the target cell. **Review Figure 7.4**
- Receptors located in the cell membrane include [ion channels](#), [protein kinases](#), and [G protein-coupled receptors](#).

ion channel An integral membrane protein that allows ions to diffuse across the membrane in which it is embedded.

protein kinase (kye' nase) An enzyme that catalyzes the addition of a phosphate group from ATP to a target protein.

G protein-coupled receptors A class of receptors that change configuration upon ligand binding such that a G protein binding site is exposed on the cytoplasmic domain of the receptor, initiating a signal transduction pathway.

- Ion channel receptors are “gated.” The gate “opens” when the three-dimensional structure of the channel protein is altered by ligand binding. **Review Figure 7.5**
- Protein kinase receptors catalyze the phosphorylation of themselves or other proteins. **Review Figure 7.6**
- A [G protein](#) has three important binding sites, which bind a G protein-coupled receptor, GDP or GTP, and an effector protein. A G protein can either activate or inhibit an [effector protein](#). **Review Figure 7.7, Animation 7.1**

G protein A membrane protein involved in signal transduction; characterized by binding GDP or GTP.

effector protein In cell signaling, a protein responsible for the cellular response to a signal transduction pathway.

- [Intracellular receptors](#) include certain photoreceptors in plants and steroid hormone receptors in animals. A lipid-soluble ligand such as a steroid hormone may enter the cytoplasm or the nucleus before binding. Many intracellular receptors are transcription factors. **Review Figure 7.8**

intracellular receptor A receptor that binds its ligand inside the cell. An example is the estrogen receptor in mammals.

7.3 The Response to a Signal Spreads through the Cell

- A **protein kinase cascade** amplifies the response to receptor binding. **Review Focus: Key Figure 7.10, Animation 7.2**
- Second messengers include [cyclic AMP \(cAMP\)](#), [inositol trisphosphate \(IP₃\)](#), [diacylglycerol \(DAG\)](#), and calcium ions. IP₃ and DAG are derived from the phospholipid [phosphatidyl inositol-bisphosphate \(PIP₂\)](#). **Review Figures 7.11, 7.12**

cyclic AMP See cAMP.

cAMP (cyclic AMP) A compound formed from ATP that acts as a second messenger.

inositol trisphosphate (IP₃) An intracellular second messenger derived from membrane phospholipids.

diacylglycerol (DAG) In hormone action, the second messenger produced by hydrolytic removal of the head group of certain phospholipids.

DAG See diacylglycerol.

phosphatidyl inositol-bisphosphate (PIP₂) A phospholipid in the cell membrane that is involved in cell signaling after a ligand binds to a nearby receptor.

- The gas nitric oxide (NO) is involved in signal transduction in human smooth muscle cells. **Review Figure 7.13**
- Signal transduction can be regulated in several ways. The balance between activating and inactivating the molecules involved determines the ultimate cellular response to a signal. **Review Figure 7.14**

▶ 7.4 Cells Change in Response to Signals in Several Ways

- The cellular responses to signals may include the opening of ion channels, the alteration of enzyme activities, or changes in gene expression.
- Activated enzymes may activate other enzymes in a signal transduction pathway, leading to impressive amplification of a signal. **Review Figure 7.15, Activity 7.2**
- Protein kinases covalently add phosphate groups to target proteins; cAMP binds target proteins noncovalently. Both kinds of binding change the target protein's shape to expose or hide a region involved in function.

▶ 7.5 Adjacent Cells in a Multicellular Organism Can Communicate Directly

- Many adjacent animal cells can communicate with one another directly through small pores in their cell membranes called **gap junctions**. Protein structures called **connexons** form thin channels between two adjacent cells through which small signal molecules and ions can pass. **Review Figure 7.16A**

gap junction A 2.7-nanometer gap between cell membranes of two animal cells, spanned by protein channels. Gap junctions allow chemical substances or electrical signals to pass from cell to cell.

connexon In a gap junction, a protein channel linking adjacent animal cells.

- Plant cells are connected by somewhat larger pores called **plasmodesmata**, which traverse both cell membranes and cell walls. The **desmotubule** narrows the opening of the plasmodesma. **Review Figure 7.16B**

plasmodesmata (singular: plasmodesma) [Gk. *plassein*: to mold + *desmos*: band] Cytoplasmic strands connecting two adjacent plant cells.

desmotubule A membrane extension connecting the endoplasmic reticulum of two plant cells that traverses the plasmodesma.

- The evolution of cell communication and tissue formation can be inferred from existing organisms, such as certain green algae. **Review Figure 7.17**

See [Activity 7.3](#) for a concept review of this chapter.

Review

- .1 A signal transduction pathway includes a signal, a receptor, and a response.
- .3 A signal transduction cascade transmits and amplifies a signal inside a cell.

Original Papers: Forst, S., J. Delgado and M. Inouye. 1989. Phosphorylation of OmpR by the osmosensor EnvZ modulates expression of the *ompF* and *ompC* genes in *Escherichia coli*. *Proceedings of the National Academy of Sciences USA* 86: 6052–6056.

Cai, S. J. and M. Inouye. 2002. EnvZ-OmpR interaction and osmoregulation in *Escherichia coli*. *Journal of Biological Chemistry* 277: 24155–24161.

Escherichia coli (**Figure A**) is a bacterium that lives in the human intestine, where it contributes to digestion by breaking down food molecules. You might think that these bacteria have a stable environment, but these microorganisms face a periodic threat. During digestion in the intestine, the solute concentrations around the bacteria fluctuate and at times exceed the solute concentration inside the cells. The cells must respond to this hypertonic environment to prevent desiccation due to water loss.

Figure A

To investigate how the bacterial cells manage this problem, researchers grew *E. coli* in two solutions. One solution was hypertonic, with a solute concentration higher than that inside the cell. The other solution was isotonic, with a solute concentration similar to that inside the cell. The researchers isolated membrane proteins from the cells and separated them according to size, using polyacrylamide gel electrophoresis. After staining the proteins on the gel, one of the membrane proteins, OmpC, showed differences depending on the environmental conditions used to grow the cells. **Figure B** shows these results. The amount of stain is proportional to the amount of protein in the gel.

Figure B

The researchers suspected that a signal transduction pathway was involved in *E. coli*'s response to a hypertonic environment. They investigated whether any proteins became phosphorylated by a protein kinase as part of such a pathway. Interesting results were noted with respect to two proteins: a membrane protein (EnvZ) and a protein found in the cytoplasm

(OmpR). After purifying EnvZ and OmpR from *E. coli*, each protein was incubated separately with ^{32}P -radiolabeled ATP. This was done to examine protein phosphorylation: proteins that are phosphorylated in the presence of ^{32}P -ATP become labeled ^{32}P . [Table A](#) summarizes the results of this experiment.

Table A

	EnvZ + ^{32}P -ATP	OmpR + ^{32}P -ATP
^{32}P label incorporated into protein	High	None

Next, the researchers tried mixing ^{32}P -radiolabeled EnvZ with OmpR. After mixing the two proteins, samples were removed from the mixture at 0, 2, 5, and 10 minutes. [Table B](#) summarizes the results.

Table B

	Time after mixing ^{32}P -EnvZ + OmpR (min)			
	0	2	5	10
^{32}P label present in EnvZ	High	Medium	Low	None
^{32}P label present in OmpR	None	Low	Medium	High

Finally, the researchers measured the quantities of EnvZ and OmpR in *E. coli* cells after they were grown under different conditions. Values in [Table C](#) are numbers of molecules per cell.

Table C

	Nutrient broth (isotonic)	Nutrient broth + 20% sucrose (hypertonic)
EnvZ	63	113
OmpR	2,043	3,525

Questions

- What evidence shows that bacterial cells respond in their membrane protein composition to changes in environmental solute concentration?
- What do the data in [Tables A](#) and [B](#) indicate about the roles of EnvZ and OmpR? Write two equations to illustrate your answer.
- What evidence suggests that signal amplification occurs in this signal transduction system?
- Draw a sketch to illustrate a possible mechanism for how this signal transduction pathway responds to a hypertonic environment. Your sketch should account for all of the data provided.

How Aspirin Works

Despite suffering from the “ague,” the Reverend Edward Stone went walking in the English countryside. Feverish, tired, with aching muscles and joints, he came across a willow tree. Although apparently unaware that many ancient healers used willow bark extracts to reduce fever, the clergyman knew of the tradition of natural remedies for various diseases. The willow reminded him of the bitter extracts from the bark of South American trees then being sold (at high prices) to treat fevers. Removing some willow bark, Stone sucked on it and found it did indeed taste bitter—and that it relieved his symptoms.

Later he gathered a pound of willow bark and ground it into a powder, which he gave to about 50 people who complained of pain; all said they felt better. Stone reported the results of this “clinical test” in a letter to the Royal Society, England’s most respected scientific body. Stone had discovered salicylic acid, the basis of the most widely used drug in the world. The date of his letter (which still exists) was April 25, 1763.

The chemical structure of salicylic acid (named for *Salix*, the willow genus) was worked out about 70 years later, and soon chemists could synthesize it in the laboratory. Although the compound alleviated pain, its acidity irritated the digestive system. In the late 1890s, the German chemical company Bayer synthesized a milder yet equally effective form, acetylsalicylic acid, which it marketed as aspirin. The new medicine’s success launched Bayer to world prominence as a pharmaceutical company, a position it maintains today.

In the 1960s and 1970s, aspirin use declined somewhat when other pain-reducing medications became widely available. But over this same time, clinical studies revealed a new use for aspirin: it is an effective anticoagulant, shown to prevent heart attacks and strokes caused by blood clots. Today many people take a daily low dose of aspirin as a preventive against clotting disorders.

Fever, joint pain, headache, blood clots: What do these symptoms have in common? They all are mediated by fatty acid products called prostaglandins and molecules derived from them. Salicylic acid blocks the synthesis of the primary prostaglandin. The biochemical mechanism by which aspirin works was described in 1971. As we will see, an understanding of this mechanism requires an understanding of protein and enzyme function—two subjects of this chapter.

How do anti-inflammatory drugs work as enzyme inhibitors?

8.1 Physical Principles Underlie Biological Energy Transformations

A **chemical reaction** occurs when atoms have sufficient energy to combine or change their bonding partners. Consider the hydrolysis of the disaccharide sucrose to its component monomers, glucose and fructose (see [p. 56](#) for the chemical structures of these sugars). We can express this reaction by a chemical equation:

chemical reaction The change in the composition or distribution of atoms of a substance with consequent alterations in properties.

In this equation, sucrose and water are the **reactants**, and glucose and fructose are the **products**. During the reaction, some of the bonds in sucrose and water are broken and new bonds are formed, resulting in products with chemical properties that are very different from those of the reactants. The sum total of all the chemical reactions occurring in a biological system at a given time is called **metabolism**. Metabolic reactions involve energy changes; for example, the energy contained in the chemical bonds of sucrose (reactants) is greater than the energy in the bonds of the two products, glucose and fructose.

reactant A chemical substance that enters into a chemical reaction with another substance.

products The molecules that result from the completion of a chemical reaction.

metabolism (meh tab' a lizm) [Gk. *metabole*: change] The sum total of the chemical reactions that occur in an organism, or some subset of that total (as in respiratory metabolism).

focus your learning

The second law of thermodynamics states that disorder is constantly increasing in the universe.

Chemical reactions in biological systems are either exergonic or endergonic.

Physicists define **energy** as the capacity to do work, which occurs when a force operates on an object over a distance. In biochemistry, it is more useful to think of energy as *the capacity for change*. In biochemical reactions, energy changes are usually associated with changes in the chemical compositions and properties of molecules.

energy The capacity to do work or move matter against an opposing force. The capacity to accomplish change in physical and chemical systems.

There are two basic types of energy

Energy comes in many forms: chemical, electrical, heat, light, and mechanical ([Table 8.1](#)). But all forms of energy can be considered as one of two basic types ([Figure 8.1](#)):

table 8.1 Energy in Biology	
Form of energy	Example in biology
Chemical: Stored in bonds	Chemical energy stored in covalent bonds is released during the hydrolysis of polymers
Electrical: Separation of charges	Electrical gradients across cell membranes help drive the movement of ions through channels
Heat: Transfer due to temperature difference	Heat can be released by chemical reactions, and this can alter the internal temperature of an organism
Light: Electromagnetic radiation stored as photons	Light energy is captured by pigments in the eye and by plant pigments in photosynthesis
Mechanical: Energy of motion	Mechanical energy is used in muscle movements and movements within cells

Figure 8.1 Energy Conversions and Work A leaping frog illustrates both the conversion between potential and kinetic energy and the conversion of energy from one form (chemical) to another (mechanical).

- **Potential energy** is the energy of state or position—that is, stored energy. It can be stored in many forms: in chemical bonds, as a concentration gradient, or even as an electric charge imbalance.
- **Kinetic energy** is the energy of movement—that is, the type of energy that does work, that makes things change. For example, heat causes molecular motions and can even break chemical bonds.

potential energy Energy not doing work but with the potential to do so, such as the energy stored in chemical bonds. (Contrast with kinetic energy.)

kinetic energy (kuh-net' ik) [Gk. *kinetos*: moving] The energy associated with movement. (Contrast with potential energy.)

Potential energy can be converted into kinetic energy and vice versa, and the form that the energy takes can also be converted. Think of reading this book: light energy is converted to chemical energy in your eyes, and then is converted to electrical energy in the nerve cells that carry messages to your brain. When you decide to turn a page, the electrical and chemical energy of nerves and muscles are converted to kinetic energy for movement of your hand and arm.

There are two basic types of metabolism

Energy changes in living systems usually occur as chemical changes, in which energy is stored in, or released from, chemical bonds.

Anabolic reactions (collectively anabolism) link smaller molecules to form larger, more complex molecules (for example, the synthesis of sucrose from glucose and fructose). Anabolic reactions require an input of energy. Energy is captured in the chemical bonds that are formed (for example, the glycosidic bond between the two monosaccharides). This captured energy is stored in the chemical bonds as potential energy:

anabolic reaction (an uh bah' lik) [Gk. *ana*: upward + *ballein*: to throw] A synthetic reaction in which simple molecules are linked to form more complex ones; requires an input of energy and captures it in the chemical bonds that are formed. (Contrast with catabolic reaction.)

Catabolic reactions (collectively catabolism) break down larger, more complex molecules into smaller ones and often release the energy stored in the chemical bonds. For example, when sucrose is hydrolyzed, energy is released. In a biological system the released energy may be recaptured in new chemical bonds, or it may be used as kinetic energy—moving atoms, molecules, cells, or the whole organism:

catabolic reaction (kat uh bah' lik) [Gk. *kata*: to break down + *ballein*: to throw] A synthetic reaction in which complex molecules are broken down into simpler ones and energy is released. (Contrast with anabolic reaction.)

Catabolic and anabolic reactions are often linked. The energy released in catabolic reactions is often used to drive anabolic reactions—that is, to do biological work. For example, the energy released by the breakdown of glucose (catabolism) is used to drive anabolic reactions such as the synthesis of triglycerides. This is why you can accumulate fat if you eat food in excess of your energy requirements.

The **laws of thermodynamics** (*thermo*, “energy,” + *dynamics*, “change”) were derived from studies of the fundamental physical properties of energy, and the ways it interacts with matter. The laws apply to all matter and all energy transformations in the universe. Their application to living systems helps us understand how organisms and cells harvest and transform energy to sustain life.

laws of thermodynamics [Gk. *thermos*: heat + *dynamis*: power] Laws derived from studies of the physical properties of energy and the ways energy interacts with matter. (See *also* first law of thermodynamics, second law of thermodynamics.)

The first law of thermodynamics: Energy is neither created nor destroyed

The first law of thermodynamics states that in any energy conversion, energy is neither created nor destroyed. In other words, during any conversion of energy, the total energy in the system under consideration before and after the conversion is the same ([Figure 8.2A](#)). As you will see in the next two chapters, the potential energy present in the chemical bonds of carbohydrates and lipids can be converted to potential energy in the form of adenosine triphosphate (ATP). This can then be converted into kinetic energy to do mechanical work (such as in muscle contractions) or biochemical work (such as protein synthesis).

(A)

The First Law of Thermodynamics

The total amount of energy before a transformation equals the total amount after a transformation. No new energy is created, and no energy is lost.

(B)

The Second Law of Thermodynamics

Although a transformation does not change the total amount of energy within a closed system (one that is not exchanging matter or energy with the surroundings), after any transformation the amount of energy available to do work is always less than the original amount of energy.

Another statement of the second law is that in a closed system, with repeated energy transformations, free energy decreases and unusable energy (disorder) increases—a phenomenon known as the increase in **entropy**.

Figure 8.2 The Laws of Thermodynamics (A) The first law states that energy cannot be created or destroyed. (B) The second law states that after energy transformations, some energy becomes unavailable to do work.

The second law of thermodynamics: Disorder tends to increase

Although energy cannot be created or destroyed, the second law of thermodynamics states that when energy is converted from one form to another, some of that energy becomes unavailable for doing work ([Figure 8.2B](#)). In other words, no physical process or chemical reaction is 100 percent efficient; some of the released energy is lost to a form associated with disorder. Think of disorder as a kind of randomness that is due to the thermal motion of particles; this energy is of such a low value and so dispersed that it is unusable. **Entropy** is a measure of the disorder in a system.

entropy (S) (en' tro pee) [Gk. *tropein*: to change] A measure of the degree of disorder in any system. Spontaneous reactions in a closed system are always accompanied by an increase in entropy.

It takes energy to impose order on a system. Unless energy is applied to a system, it will be randomly arranged or disordered. The second law applies to all energy transformations, but we

will focus here on chemical reactions in living systems.

NOT ALL ENERGY CAN BE USED

In any system, the total energy includes the usable energy that can do work and the unusable energy that is lost to disorder:

$$\text{Total energy} = \text{usable energy} + \text{unusable energy}$$

In biological systems, the total energy is called **enthalpy** (H). The usable energy that can do work is called **free energy** (G). Free energy is what cells require for all the chemical reactions involved in growth, cell division, and maintenance. The unusable energy is represented by entropy (S) multiplied by the absolute temperature (T). Thus we can rewrite the word equation above more precisely as:

enthalpy (H) The total energy of a system.

free energy (G) Energy that is available for doing useful work, after allowance has been made for the increase or decrease of disorder.

$$H = G + TS \quad (8.1)$$

Because we are interested in usable energy, we rearrange [Equation 8.1](#):

$$G = H - TS \quad (8.2)$$

Although we cannot measure G , H , or S absolutely, we can determine the change in each at a constant temperature. Such energy changes are measured in calories (cal) or joules (J).¹ A change (in energy, or another quantity) is represented by the Greek letter delta (Δ). The change in free energy (ΔG) of any chemical reaction is equal to the difference in free energy between the products and the reactants:

$$\Delta G_{\text{reaction}} = G_{\text{products}} - G_{\text{reactants}} \quad (8.3)$$

A change in free energy can be either positive or negative; that is, the free energy of the products can be more or less than the free energy of the reactants. If the products have more free energy than the reactants, then there must have been some input of energy into the reaction. (Remember that energy cannot be created, so some energy must have been added from an external source.)

At a constant temperature ΔG is defined in terms of the change in total energy (ΔH) and the change in entropy (ΔS):

$$\Delta G = \Delta H - T\Delta S \quad (8.4)$$

[Equation 8.4](#) tells us whether free energy is released or required by a chemical reaction:

If ΔG is negative ($\Delta G < 0$), free energy is released.

If ΔG is positive ($\Delta G > 0$), free energy is required.

If the necessary free energy is not available, the reaction does not occur. The sign and magnitude of ΔG depend on the two factors on the right side of the equation:

- ΔH : In a chemical reaction, ΔH is the total amount of energy added to the system ($\Delta H > 0$) or released ($\Delta H < 0$).
- ΔS : Depending on the sign and magnitude of ΔS , the entire term, $T\Delta S$, may be negative or positive, large or small. In other words, in living systems at a constant temperature (no change in T), the magnitude and sign of ΔG can depend a lot on changes in entropy.

If a chemical reaction increases entropy, its products are more disordered or random than its reactants. If there are more products than reactants, as in the hydrolysis of a protein to its amino acids, the products have considerable freedom to move around. The disorder in a solution of amino acids will be large compared with that in the protein, in which peptide bonds and other forces prevent free movement. So in hydrolysis, the change in entropy (ΔS) will be positive. Conversely, if there are fewer products and they are more restrained in their movements than the reactants (as for amino acids being joined in a protein), ΔS will be negative.

DISORDER TENDS TO INCREASE

The second law of thermodynamics also predicts that as a result of transformations involving energy, disorder tends to increase; some energy is always lost to random thermal motion (entropy). Chemical changes, physical changes, and biological processes all tend to increase entropy (see [Figure 8.2B](#)), and this explains why some reactions proceed in one direction rather than another.

How does the second law apply to organisms? Consider the human body, with its highly organized tissues and organs composed of large, complex molecules. You might think that this order and complexity are in conflict with the second law—after all, entropy, or disorder, should be maximized—but they are not for two reasons:

- . *Getting ordered is coupled to the generation of disorder.* Making 1 kg of a human body (soft tissues, not bones) requires the catabolism of about 10 kg of highly ordered biological materials (our food), which are converted into CO_2 , H_2O , and other simple molecules. So this process creates far more disorder (more energy is lost to entropy in the small molecules) than the amount of order (total energy; enthalpy) stored in large molecules in 1 kg of a person.
- . *Life requires a constant input of energy to maintain order.* Without this energy, the complex structures of living systems would break down. Because energy is used to generate and maintain order, there is no conflict with the second law of thermodynamics.

Having seen that the laws of thermodynamics apply to organisms, let's see how these laws apply to biochemical reactions inside the cell.

Chemical reactions release or consume energy

As you saw earlier, anabolic reactions link simple molecules to form more complex molecules, so they tend to increase complexity (order) in the cell. By contrast, catabolic reactions break down complex molecules into simpler ones, so they tend to decrease complexity (generate disorder).

Catabolic reactions may break down an ordered reactant into smaller, more randomly distributed products. Reactions that release free energy ($-\Delta G$) are called **exergonic** reactions ([Figure 8.3A](#)). For example:

exergonic A chemical reaction in which the products of the reaction have lower free energy than the reactants, resulting in a release of free energy. (Contrast with endergonic.)

Figure 8.3 Exergonic and Endergonic Reactions (A) In an exergonic reaction, the reactants behave like a ball rolling down a hill, and energy is released. (B) A ball will not roll uphill by itself. Driving an endergonic reaction, like moving a ball uphill, requires the addition of free energy.

Complex molecules $\rightarrow$ free energy + small molecules

Anabolic reactions may make a single product (a highly ordered substance) out of many smaller reactants (less ordered). Reactions that require or consume free energy ($+\Delta G$) are called **endergonic** reactions (Figure 8.3B). For example:

endergonic A chemical reaction in which the products have higher free energy than the reactants, thereby requiring free energy input to occur. (Contrast with exergonic.)

Free energy + small molecules $\rightarrow$ complex molecules

In principle, chemical reactions are reversible and can run both forward and backward. For example, if compound A can be converted into compound B ($A \rightarrow B$), then B, in principle, can be converted into A ($B \rightarrow A$), although *the concentrations of A and B determine which of these directions will be favored*. You can think of the overall reaction as resulting from competition between the forward and reverse reactions ($A \rightleftharpoons B$). According to the law of mass action, increasing the concentration of A makes the forward reaction ($A \rightarrow B$) happen more often than

the reverse reaction, just as increasing the concentration of B favors the reverse reaction ($B \rightarrow A$).

There are concentrations of A and B at which the forward and reverse reactions take place at the same rate. At these concentrations, no further net change in the system is observable, although individual molecules are still forming and breaking apart. This balance between forward and reverse reactions is known as **chemical equilibrium**. **Chemical equilibrium** is a state of no net change, and a state in which $\Delta G = 0$.

chemical equilibrium See equilibrium.

chemical equilibrium See equilibrium.

Chemical equilibrium and free energy are related

Every chemical reaction proceeds to a certain extent, but not necessarily to completion (all reactants converted into products). Each reaction has a specific equilibrium point, which is related to the relative free energy content of the reactants and products. To understand the principle of equilibrium, let's consider the following example, which takes place inside most cells but which we can do in the lab. This is the interconversion of glucose 1-phosphate and glucose 6-phosphate, a rearrangement of a phosphate group from one position on the ring of carbon atoms to another:

Imagine that we start out with an aqueous solution of glucose 1-phosphate that has a concentration of 0.02 M. (M stands for molar concentration; see [Key Concept 2.4](#).) The solution is maintained under constant environmental conditions (25°C and pH 7). As the reaction proceeds to equilibrium, the concentration of the product, glucose 6-phosphate, rises from 0 M to 0.019 M, while the concentration of the reactant, glucose 1-phosphate, falls from 0.02 M to 0.001 M, at which point, equilibrium is reached ([Figure 8.4](#)). *At equilibrium, the reverse reaction, from glucose 6-phosphate to glucose 1-phosphate, progresses at the same rate as the forward reaction.*

Figure 8.4 Chemical Reactions Run to Equilibrium No matter what quantities of glucose 1-phosphate and glucose 6-phosphate are dissolved in water, when equilibrium is attained, there will always be 95 percent glucose 6-phosphate and 5 percent glucose 1-phosphate.

At equilibrium, then, this reaction has a product-to-reactant ratio of 19:1 (0.019/0.001), so the forward reaction has gone 95 percent of the way to completion (“to the right,” as written above). This result is obtained every time the experiment is run under the same conditions.

The change in free energy (ΔG) for any reaction is related directly to its point of equilibrium. The further toward completion the point of equilibrium lies, the more free energy is released. In an exergonic reaction, ΔG is a negative number. The total value of ΔG also depends on the beginning concentrations of the reactants and products and other conditions such as temperature, pressure, and pH of the solution. Biochemists often calculate ΔG using standard laboratory conditions: 25°C, one atmosphere pressure, one molar (1 M) concentrations of the solutes, and pH 7. The **standard free energy change** calculated using these conditions is designated ΔG^0 . In our example of the conversion of glucose 1-phosphate to glucose 6-phosphate, $\Delta G^0 = -1.7$ kcal/mol, or -7.1 kJ/mol.

standard free energy The energy associated with a chemical reaction that can be used to do work. The sum of the enthalpy and the product of temperature and entropy.

A large, positive ΔG for a reaction means that it does not proceed to the right ($A \rightarrow B$). If the concentration of B is initially high relative to that of A, such a reaction runs “to the left” ($A \leftarrow B$), and at equilibrium nearly all of B is converted into A. A ΔG value near zero is characteristic of a readily reversible reaction: reactants and products have almost the same free energies.

In [Chapters 9](#) and [10](#) you will learn the biochemical conversions that extract energy from food and light. In turn, this energy is used to synthesize carbohydrates, lipids, and proteins. All of the chemical reactions carried out by living organisms are governed by the principles of

8.1 recap

Two laws of thermodynamics govern energy transformations in biological systems. A biochemical reaction can release or consume energy, and it may not run to completion, but instead end up at a point of equilibrium.

learning outcomes

You should be able to:

- Apply the second law of thermodynamics to biological systems.
- Differentiate between exergonic and endergonic reactions.

1. What is the difference between endergonic and exergonic reactions, and what is the importance of positive and negative ΔG ?
2. What makes it possible for endergonic reactions to proceed in organisms?

The principles of thermodynamics that we have been discussing apply to all energy transformations in the universe, so they are very powerful and useful. Now let's apply them to reactions in cells that involve the currency of biological energy, ATP.

¹A calorie is the amount of heat energy needed to raise the temperature of 1 gram of pure water from 14.5°C to 15.5°C. In the SI system, energy is measured in joules. 1 J = 0.239 cal; conversely, 1 cal = 4.184 J. Thus, for example, 486 cal = 2,033 J, or 2.033 kJ. Although they are defined here in terms of heat, the calorie and the joule are measures of mechanical, electrical, or chemical energy. When you compare data on energy, always compare joules with joules and calories with calories.

8.2 ATP Plays a Key Role in Biochemical Energetics

Cells use adenosine triphosphate (ATP) for the capture and transfer of the free energy they require to do chemical work. ATP operates as a kind of “energy currency.” Just as it is more efficient and convenient for you to trade money for a lunch in a café than to trade your actual labor, it’s useful for cells to have a single currency for transferring energy between different reactions and cell processes. So some of the free energy that is released by exergonic reactions is captured in the formation of ATP from adenosine diphosphate (ADP) and inorganic phosphate (HPO_4^{2-} , which is commonly abbreviated to P_i). The ATP can then be hydrolyzed in the cell to release free energy to drive endergonic reactions. (In some reactions, guanosine triphosphate [GTP] is used as the energy transfer molecule instead of ATP, but we will focus on ATP here.)

focus your learning

ATP releases usable energy for a cell when hydrolyzed to ADP and P_i .

Through coupling reactions, ATP drives endergonic reactions using energy derived from exergonic reactions.

ATP has another important role in the cell beyond its use as an energy currency: it can be converted into a building block for nucleic acids (see [Chapter 4](#)). The structure of ATP is similar to that of other nucleoside triphosphates, but two things about ATP make it especially useful to cells:

- ATP releases a relatively large amount of energy when hydrolyzed to ADP and P_i .
- ATP can phosphorylate (donate a phosphate group to) many different molecules, which gain some of the energy that was stored in the ATP.

ATP hydrolysis releases energy

An ATP molecule consists of the nitrogenous base adenine bonded to ribose (a sugar), which is attached to a sequence of three phosphate groups ([Figure 8.5A](#)). The hydrolysis of a molecule of ATP yields free energy, as well as ADP and an inorganic phosphate ion (P_i). Thus:

The structure of ATP

Forming ADP and P_i results in a lower free energy state, and energy is released.

Figure 8.5 ATP ATP is richer in energy than its relatives ADP and AMP.

Activity 8.1 ATP and Coupled Reactions www.Life11e.com/ac8.1

The important property of this reaction is that it is exergonic, releasing free energy. Under standard laboratory conditions, the change in free energy (ΔG) for this reaction is about -7.3 kcal/mol (-30 kJ/mol). However, under cellular conditions ΔG can be as much as -14 kcal/mol. We give both values here because you will encounter them both and you should be aware of their origins. Both are correct, but in different conditions.

A molecule of ATP can be hydrolyzed either to ADP and P_i , or to adenosine monophosphate (AMP) and a pyrophosphate ion ($P_2O_7^{4-}$; commonly abbreviated as PP_i). Two characteristics of ATP account for the free energy released by the loss of one or two of its phosphate groups:

- Because phosphate groups are negatively charged and so repel each other, it takes energy to get two phosphates near enough to each other to make the covalent bond that links them together. Some of this energy is stored as potential energy in the $P\sim O$ bonds between the phosphates in ATP (the wavy line indicates a high-energy bond).
- The free energy of this $P\sim O$ bond (called a phosphoric acid anhydride bond) is much higher than the energy of the $O-H$ bond that forms as a result of hydrolysis. So it is the lower free energy state of the system that releases energy.

Cells use the energy released by ATP hydrolysis to fuel endergonic reactions (such as the biosynthesis of complex molecules), for active transport, for movement, and even for the production of light (bioluminescence). Another interesting example of the use of ATP involves converting its chemical energy into light energy.

 Media Clip 8.1 **Bioluminescence in the Deep Sea** www.Life11e.com/mc8.1

ATP couples exergonic and endergonic reactions

As you have just seen, the hydrolysis of ATP is exergonic and yields ADP, P_i , and more free energy (or AMP, PP_i , and more free energy). The reverse reaction, the formation of ATP from ADP and P_i , is endergonic and consumes as much free energy as is released by the hydrolysis of ATP:

Many exergonic reactions in the cell can provide the energy to convert ADP into ATP. For eukaryotes and many prokaryotes, the most important of these reactions is cellular respiration, in which some of the energy released from fuel molecules is captured in ATP. The formation and hydrolysis of ATP constitute what might be called an “energy-coupling cycle,” in which ADP picks up energy from exergonic reactions to become ATP, which then donates energy to endergonic reactions. ATP is the common component of these reactions and is the agent of coupling, as illustrated in [Figure 8.6](#).

Figure 8.6 Coupling of Reactions Exergonic cellular reactions release the energy needed to make ATP from ADP. The energy released from the conversion of ATP back to ADP can be used to fuel endergonic reactions.

Coupling of exergonic and endergonic reactions is very common in metabolism. Free energy is captured and retained in the P~O bonds of ATP. ATP then diffuses to another place in the cell, where its hydrolysis releases the free energy to drive an endergonic reaction. For example, the formation of glucose 6-phosphate from glucose ([Figure 8.7](#)), which has a positive ΔG (is endergonic), will not proceed without the input of free energy from ATP hydrolysis, which has a negative ΔG (is exergonic). The overall ΔG for the coupled reactions (when the two ΔG s are added together) is negative. Hence the reactions proceed exergonically when they are coupled by occurring at the same time and place, and glucose 6-phosphate is synthesized. As you will see in [Chapter 9](#), this is the initial reaction in the catabolism of glucose.

Figure 8.7 Coupling of ATP Hydrolysis to an Endergonic Reaction The addition of phosphate derived from the hydrolysis of ATP to glucose forms the molecule glucose 6-phosphate (in a reaction catalyzed by hexokinase). ATP hydrolysis is exergonic and the energy released drives the second reaction, which is endergonic.

Q: What would be the magnitude of the ΔG of a different conversion that could drive the synthesis of ATP?

An active cell requires the production of millions of molecules of ATP per second to drive its biochemical machinery. From previous chapters, you may already be familiar with some of the activities in the cell that require energy from the hydrolysis of ATP:

Active transport across a membrane (see [Figure 6.14](#))

Condensation reactions that use enzymes to form polymers (see [Figure 3.4A](#))

Modifications of cell signaling proteins by protein kinases (see [Figure 7.15](#))

Motor proteins that move vesicles along microtubules (see [Figure 5.19](#))

An ATP molecule is typically consumed within a second of its formation. At rest, an average

person produces and hydrolyzes about 40 kg of ATP per day—as much as some people weigh. This means that each ATP molecule undergoes about 10,000 cycles of synthesis and hydrolysis every day!

8.2 recap

ATP is the “energy currency” of cells. Potential energy is stored in the P~O bonds of ATP. Some of the free energy released by exergonic reactions can be captured in the form of ATP. This energy can then be released by ATP hydrolysis and used to drive endergonic reactions.

learning outcomes

You should be able to:

- Explain the characteristics of ATP that account for the high free energy released during its hydrolysis to form ADP and P_i .
- Analyze evidence to identify reactions as exergonic or endergonic.
- Predict biochemical transformations that require coupling to ATP hydrolysis.

1. What chemical properties allow ATP to store energy?
2. The following is a biochemical reaction that involves ATP: Phosphoenolpyruvate $\rightarrow$ pyruvate ($\Delta G = +10$ kcal/mol)
 - a. Is the reaction exergonic or endergonic?
 - b. Is ATP hydrolyzed or formed during the reaction?

ATP is synthesized and used up very rapidly. But these biochemical reactions—and nearly all the others that take place inside a cell—could not proceed so rapidly without the help of enzymes.

8.3 Enzymes Speed Up Biochemical Transformations

When we know the change in free energy (ΔG) of a reaction, we know where the equilibrium point of the reaction lies: the more negative the ΔG value is, the further the reaction proceeds to products and toward completion. However, ΔG tells us nothing about the *rate* of a reaction—how fast it moves toward equilibrium. When we measure reaction rates of biochemical reactions in the lab, it quickly becomes apparent that in terms of the rapid needs for the chemistry of life, reaction rates are very slow—in fact, so slow that the cells would not survive without a way to speed up the reactions. That is the role of catalysts: substances that speed up reactions without themselves being permanently altered. A catalyst does not cause a reaction to occur that would not proceed without it, *but merely increases the rate of the reaction*, allowing equilibrium to be approached more rapidly. This is an important point: *No catalyst makes a reaction occur that cannot otherwise occur.*

focus your learning

Catalysts speed up the rate of a reaction but do not allow the occurrence of a reaction that would not otherwise take place.

Most enzymes are protein catalysts, and all enzymes have active sites where specific reactants called substrates bind and react to form products that diffuse away.

Enzymes do not alter the equilibrium point or free energy change in a reaction.

Most biological catalysts are proteins called enzymes. A biological catalyst is a molecular framework or scaffold within which chemical catalysis takes place. The enzyme binds the reactants and sometimes participates in the reaction itself; however, such participation does not permanently change the enzyme. That's the hallmark of any catalyst: It ends up in exactly the same chemical condition after a reaction as before it.

In this section we will discuss the energy barrier that controls the rate of a chemical reaction. Then we will focus on the roles of enzymes: how they interact with specific reactants, how they lower the energy barrier, and how they permit reactions to proceed more quickly.

To speed up a reaction, an energy barrier must be overcome

An exergonic reaction may release free energy, but without a catalyst it will take place very slowly because there is an energy barrier between reactants and products. Think about the hydrolysis of sucrose, which we described in [Key Concept 8.1](#):

In your body, this reaction is part of digestion. Even if water is abundant, the sucrose molecule will only very rarely bind the H atom and the —OH group of water at the appropriate locations to break the covalent bond between glucose and fructose *unless there is an input of energy to initiate the reaction*. Such an input of energy will place the sucrose into a reactive mode called the [transition state](#). The energy input required for sucrose to reach this state is called the [activation energy \(\$E_a\$ \)](#). Here's a more familiar example that can show you the ideas of activation energy and transition state:

transition state In an enzyme-catalyzed reaction, the reactive condition of the substrate after there has been sufficient input of energy (activation energy) to initiate the reaction.

activation energy (E_a) The energy barrier that blocks the tendency for a chemical reaction to occur.

Fireworks don't start exploding until you give them a spark: that's the activation energy. It excites the molecules in the fireworks so they will react with oxygen in the air. Once the transition state is reached, the explosive reaction occurs.

Generally, exergonic reactions proceed only after the reactants are pushed over the energy barrier by some added energy. The energy barrier thus represents the amount of energy needed to start the reaction, the activation energy (**Focus: Key Figure 8.8A**). Recall the ball rolling down the hill in [Figure 8.3A](#). The ball has a lot of potential energy at the top of the hill. However, if it is stuck in a small depression, it will not roll down the hill, even though that action is exergonic. To start the ball rolling, a small amount of energy (activation energy) is needed to push it out of the depression (**Focus: Key Figure 8.8B**). In a chemical reaction, the activation energy is the energy needed to change the reactants into unstable molecular forms called transition-state intermediates.

focus: key figure

(A)

E_a is the activation energy required for a reaction to begin.

ΔG for the reaction is not affected by E_a .

Figure 8.8 Activation Energy Initiates Reactions(A) In any chemical reaction, an initial stable state must become less stable before change is possible. (B) A ball on a hillside provides a physical analogy for the biochemical principle graphed in (A).

Q: Would activation energy be required for an endergonic reaction?

Transition-state intermediates have higher free energies than either the reactants or the products. Their bonds may be stretched and therefore unstable. Although the amount of activation energy needed for different reactions varies, it is often small compared with the change in free energy of the overall reaction. The activation energy put in to start a reaction is recovered during the ensuing “downhill” phase of the reaction, so it is not a part of the net free energy change, ΔG (see [Figure 8.8A](#)).

transition-state intermediate Unstable molecule in a reaction which is formed during the reaction when reactants change into products.

Where does activation energy come from? If reactants are at the human body temperature (37°C), they are moving around. A few are moving fast enough that their kinetic energy can overcome the energy barrier, enter the transition state, and react. So the reaction takes place—

but very slowly. If the system is heated, all the reactant molecules move faster and have more kinetic energy, and the reaction speeds up. You have probably used this method in the chemistry laboratory or the kitchen.

However, adding heat to increase the average kinetic energy of the molecules so they can react would not work in living systems. Such a nonspecific approach would accelerate all chemical reactions, including destructive ones such as the denaturation of proteins (see [Chapter 3](#)). A more effective way to speed up a reaction in a living system is to lower the energy barrier by bringing the reactants close together. In living cells, enzymes accomplish this task.

Enzymes bind specific reactants at their active sites

Catalysts increase the rates of chemical reactions. Most nonbiological catalysts are nonspecific. For example, powdered platinum catalyzes virtually any reaction in which molecular hydrogen (H_2) is a reactant. In contrast, most biological catalysts are highly specific. An ***enzyme** usually recognizes and binds to only one or a few closely related reactants, yielding specific products.

In an enzyme-catalyzed reaction, the reactants are called **substrates**. Substrate molecules bind to a particular place on the enzyme protein called the **active site**, where catalysis takes place ([Figure 8.9](#)). The specificity of an enzyme in speeding up a particular reaction results from the exact three-dimensional shape and structure of its active site, into which only a narrow range of substrates can fit. Other molecules—with different shapes, different functional groups, and different properties—cannot fit properly and bind to the active site. This specificity is comparable to the specific binding of a membrane transport protein or receptor protein to its specific ligand, as described in [Chapters 6](#) and [7](#).

substrate (sub' strayte) (1) The molecule or molecules on which an enzyme exerts catalytic action. (2) The base material on which a sessile organism lives.

active site The region on the surface of an enzyme or ribozyme where the substrate binds, and where catalysis occurs.

Figure 8.9 Enzyme and Substrate A reaction involving an enzyme is illustrated by lysozyme. Lysozyme catalyzes breakage of bonds in the peptidoglycans of bacterial cell walls. (See [Key Concept 5.2](#) for a description of peptidoglycans.)

The names of enzymes often reflect their functions and end with the suffix “ase.” For example, the enzyme sucrase catalyzes the hydrolysis of sucrose, which we have referred to above:

Thousands of enzymes have been identified, each catalyzing the transformation of its particular substrate(s). In general, enzymes fall into six categories:

- *Oxidoreductases* transfer electrons between molecules, especially in energy metabolism. An example of an enzyme that catalyzes this reaction is oxidoreductase:

You will see other examples in the next two chapters.

Transferases transfer groups of atoms (functional groups) (see [Figure 3.1](#)) between molecules. The basic reaction can be shown as:

where A = the donor, B = the acceptor, and X = the functional group. For example, aminotransferases transfer $-NH_2$ groups between molecules, linking carbohydrates and amino acids.

Hydrolases add water to covalent bonds to break down molecules. An example (shown above) is sucrase, which hydrolyzes sucrose to its constituent monosaccharides.

Lyases catalyze the breaking of various chemical bonds by means other than hydrolysis and oxidation, often forming a new double bond or a new ring structure. For example, a lyase catalyzes the cleavage of the phosphorus–oxygen bond of ATP:

Isomerases move functional groups from one place to another within a molecule, forming an isomer with the same atoms, differently bonded. For example, glucose and fructose are isomers of $C_6H_{12}O_6$ (see [Figure 3.17](#)).

Ligases join two molecules together. You will see examples of ligases when you learn about DNA replication in [Chapter 13](#).

A special note on language: When biologists refer to an enzyme, they usually use a verb for its action. For example, as noted above (#6), we used the words “ligases join...” It is important for you to realize that this wording is shorthand for what really happens: ligases catalyze the joining. Enzymes don’t “do” the reaction; they catalyze it.

When a substrate binds to the active site of an enzyme, the result is called an **enzyme–substrate complex (ES)** (see [Figure 8.9](#)). The ***chemical forces** that hold the complex together may include hydrogen bonding, electrical attraction, or temporary covalent bonding. The enzyme–substrate complex gives rise to product and free enzyme:

enzyme–substrate complex (ES) An intermediate in an enzyme-catalyzed reaction; consists of the enzyme bound to its substrate(s).

where E is the enzyme, S is the substrate, P is the product, and ES is the enzyme–substrate complex. The free enzyme (E) is in the same chemical form at the end of the reaction as at the beginning. While bound to the substrate, it may change chemically, but by the end of the reaction it has been restored to its initial form and is ready to bind more substrate.

The relationship between enzyme and substrate may seem familiar; it is analogous to the binding of a receptor and ligand that we described in [Chapter 7](#). In that instance, we described the affinity of a receptor for its ligand with the dissociation constant (K_D). The lower the K_D , the tighter the binding. For enzymes and their substrates, K_D values are often in the range 10^{-5} to 10^{-6} M, which favors the formation of the ES. In practical terms, the K_D values of the ES are such that the binding between enzyme and substrate is somewhat reversible; the substrate can

be released before the reaction. However, many enzyme-catalyzed reactions will proceed because the ES is short-lived and the product(s) form quickly.

Enzymes lower the energy barrier but do not affect equilibrium

Reactants that are bound to the enzyme, forming an enzyme–substrate complex, require less activation energy than do the transition-state intermediates in the corresponding uncatalyzed reaction ([Figure 8.10](#)). Thus the enzyme lowers the energy barrier for the reaction—it offers the reaction an easier path, speeding it up. When an enzyme lowers the energy barrier, both the forward and the reverse reactions speed up, so the enzyme-catalyzed reaction proceeds toward equilibrium more rapidly than the uncatalyzed reaction. *The final equilibrium is the same with or without the enzyme.* Similarly, adding an enzyme to a reaction does not change the difference in free energy (ΔG) between the reactants and the products (see [Figure 8.10](#)).

Figure 8.10 Enzymes Lower the Energy Barrier Although the activation energy is lower in an enzyme-catalyzed reaction than in an uncatalyzed reaction, the energy released is the same with or without catalysis. In other words, E_a is lower but ΔG is unchanged. Lower activation energy means the reaction will take place at a faster rate.

Activity 8.2 Free Energy Changes www.Life11e.com/ac8.2

Enzymes can change the rate of a reaction substantially. For example, if a particular protein that has arginine as its terminal amino acid just sits in solution, the protein molecules tend toward disorder and the terminal peptide bonds break, releasing the arginine residues (ΔS increases). Without an enzyme, this is a very slow reaction—it takes about 7 years for half of the protein molecules to undergo the reaction. But, with the enzyme carboxypeptidase A catalyzing the reaction, half the arginines are released in less than a second! Rate enhancement by enzymes varies from 1 million times to an amazing 10^{26} by sulfate monoesterases. The consequence of catalysis for living cells is not difficult to imagine. Such increased reaction rates make new realities possible.

8.3 recap

A chemical reaction requires a “push” over the energy barrier to get started. An enzyme reduces the activation energy needed to start a reaction by binding the reactants (substrates), which speeds up the reaction. Biological catalysts are highly specific; only a

narrow range of substrates can fit into the enzyme's active site, so generally only one specific reaction can be catalyzed by a given enzyme. Enzymes affect only the *rates* at which reactions proceed—they do not affect the equilibrium or free energy associated with a given reaction.

learning outcomes

You should be able to:

- Describe a catalyst.
 - Describe how an enzyme-substrate complex forms.
 - Describe the relationship between an enzyme and the equilibrium point of the reaction it catalyzes.
-
1. Explain how the structure of an enzyme makes that enzyme specific.
 2. What is the relationship between an enzyme and the equilibrium point of a reaction?
 3. When potatoes are peeled, the enzyme polyphenol oxidase causes discoloration by catalyzing the oxidation of certain molecules, using O_2 as a substrate. Explain these observations:
 - a. Browning is reduced in potatoes that are peeled under water and kept there.
 - b. Potatoes that have been boiled at 100°C and then cooled do not brown when they are sliced.

Now that you have a general understanding of the structures, functions, and specificities of enzymes, let's look more closely at how they work.

***connect the concepts** To understand enzymes and their activity, you must first understand the structures and chemical properties of proteins. See [Key Concept 3.2](#).

***connect the concepts** Binding of a substrate to an enzyme involves not just a “fit” but also noncovalent interactions between the enzyme and substrate. See [Key Concept 3.2](#) for an outline of noncovalent interactions.

8.4 Enzymes Bring Substrates Together so Reactions Readily Occur

During and after the formation of the enzyme–substrate complex, chemical interactions occur. These interactions contribute directly to the breaking of old bonds and the formation of new ones. In catalyzing a reaction, an enzyme may use one or more strategies.

focus your learning

Several different mechanisms enable enzymes to speed up chemical reactions.

An enzyme may undergo a change in shape called induced fit as the result of binding its substrate.

Many enzymes require additional chemical partners to catalyze a chemical reaction

The concentration of substrate influences the rate of an enzyme-catalyzed reaction

Enzymes can orient substrates

When free in solution, substrates are moving from place to place randomly while at the same time vibrating, rotating, and tumbling around. They may not have the proper orientation to interact when they collide. Part of the activation energy needed to start a reaction is used to bring together specific atoms so that bonds can form ([Figure 8.11A](#)). For example, if acetyl CoA and oxaloacetate are to form citrate (a step in the metabolism of glucose; see [Key Concept 9.2](#)), the two substrates must be oriented so that the carbon atom of the methyl group of acetyl CoA can form a covalent bond with the carbon atom of the carbonyl group of oxaloacetate. The active site of the enzyme citrate synthase has just the right shape to bind these two molecules so that these atoms are adjacent.

(B) Physical strain

(C) Chemical charge

Figure 8.11 Life at the Active Site Enzymes use several mechanisms to cause their substrates to enter the transition state: (A) orientation, (B) physical strain, and (C) chemical charge.

Enzymes can induce strain in the substrate

Once a substrate has bound to its active site, an enzyme can cause bonds in the substrate to stretch, putting it in an unstable transition state ([Figure 8.11B](#)). For example, lysozyme is a protective enzyme abundant in tears and saliva that destroys invading bacteria by cleaving peptidoglycans in their cell walls. Lysozyme's active site "stretches" the bonds between the glycan monomers, rendering the bonds unstable and more reactive to lysozyme's other substrate, water.

Enzymes can temporarily add chemical groups to substrates

The side chains (R groups) of an enzyme's amino acids may be direct participants in making the enzyme's substrates more chemically reactive ([Figure 8.11C](#)).

In *acid-base catalysis*, the acidic or basic side chains of the amino acids in the active site transfer H^+ to or from the substrate, destabilizing a covalent bond in the substrate, and permitting it to break.

In *covalent catalysis*, a functional group in a side chain forms a temporary covalent bond with a portion of the substrate.

In *metal ion catalysis*, metal ions such as copper, iron, and manganese, which are often firmly bound to side chains of enzymes, can lose or gain electrons without detaching from the

enzymes. This ability makes them important participants in oxidation–reduction reactions, which involve the loss or gain of electrons.

Molecular structure determines enzyme function

Many enzymes are much larger than their substrates. An enzyme is typically a protein containing hundreds of amino acids. It may consist of a single folded polypeptide chain or of several subunits (see [Key Concept 3.2](#)). Its substrate is generally a small molecule or a small part of a large molecule. The active site of the enzyme is usually quite small, not more than 6 to 12 amino acids. You may be asking yourself:

What features of the enzyme's active site allow it to recognize and bind the substrate?

What is the role of the rest of the protein?

THE ACTIVE SITE IS SPECIFIC TO THE SUBSTRATE(S)

The remarkable ability of an enzyme to select exactly the right substrate(s) depends on a precise interlocking of molecular shapes and interactions of chemical groups at the active site. The binding of a substrate to the active site depends on the same kinds of forces that maintain the tertiary structure of the enzyme: hydrogen bonds, the attraction and repulsion of electrically charged groups, and hydrophobic interactions. The specific fit of the substrate in the active site of lysozyme is illustrated in [Figures 8.9](#) and [8.11B](#).

AN ENZYME CHANGES SHAPE WHEN IT BINDS A SUBSTRATE

Just as a membrane receptor protein may undergo precise changes in conformation upon binding to its ligand (see [Chapter 7](#)), some enzymes change their shapes when they bind their substrate(s). These shape changes, which are called **induced fit**, alter the shape of the active site(s) of the enzyme.

induced fit A change in the shape of an enzyme caused by binding to its substrate that exposes the active site of the enzyme.

An example of induced fit can be seen in the enzyme hexokinase (see [Figure 8.7](#)), which catalyzes the reaction

Induced fit brings reactive side chains from the hexokinase active site into alignment with the substrates ([Figure 8.12](#)), facilitating its catalytic mechanisms. Equally important, the folding of hexokinase to fit around the substrates (glucose and ATP) excludes water from the active site. This is essential, because if water were present, the ATP could be hydrolyzed to ADP and P_i . But since water is absent, the transfer of a phosphate from ATP to glucose is favored.

Figure 8.12 Some Enzymes Change Shape When Substrate Binds to Them

Shape changes result in an induced fit between enzyme and substrate, improving the catalytic ability of the enzyme. Induced fit can be observed in the enzyme hexokinase, seen here with and without its substrates, glucose (red) and ATP (yellow).

Q: Do covalent bonds in hexokinase break when it changes shape? Explain.

Induced fit at least partly indicates what the role(s) of the rest of the protein may be:

It provides a framework so that the amino acids of the active site are properly positioned in relation to the substrate(s).

It participates in significant changes in protein shape and structure that result in induced fit.

It provides binding sites for regulatory molecules (see [Key Concept 8.5](#)).

Not all enzymes are proteins

For most of the twentieth century, biologists thought that all enzymes were proteins. After all, they reasoned, only proteins have the diversity of three-dimensional structures and functional groups to bind to substrates and catalyze their transformations (review [Key Concept 3.2](#)). Then it was discovered that some RNA molecules can act as enzymes by catalyzing changes in substrates, in most cases other RNA molecules. You will learn about RNA splicing in [Key Concept 14.4](#). Briefly, this involves a cell making a larger RNA that gets cut and spliced to remove internal region(s). The splicing reaction is catalyzed by a ribozyme. Another important ribozyme occurs at the ribosome, where an RNA molecule catalyzes the formation of a peptide bond between amino acids (see [Key Concept 14.5](#)).

In retrospect, it is not too surprising that some RNA molecules can act as biological catalysts ([ribozymes](#)). As you saw in [Figure 4.3](#), most RNAs are single strands of nucleotides that can fold back on themselves and form a three-dimensional structure by hydrogen bonding. A substrate can fit into the RNA structure, and functional groups on the RNA (such as —NH_2 and C=O) can be involved in catalysis.

ribozyme An RNA molecule with catalytic activity.

Some enzymes require other molecules in order to function

Many enzymes require the presence of nonprotein chemical “partners” in order to function ([Table 8.2](#)):

table 8.2 Some Examples of Nonprotein “Partners” of Enzymes	
Type of molecule	Role in catalyzed reactions
Prosthetic groups	
Heme	Binds ions, O ₂ , and electrons
FAD	Carries electrons/protons
Retinal	Converts light energy
Inorganic cofactors	
Iron (Fe ²⁺ or Fe ³⁺)	Oxidation/reduction
Copper (Cu ⁺ or Cu ²⁺)	Oxidation/reduction
Zinc (Zn ²⁺)	Stabilizes DNA binding structure
Coenzymes	
Biotin	Carries —COO [−]
Coenzyme A	Carries —CO—CH ₃
NAD	Carries electrons/protons
ATP	Provides/extracts energy

Prosthetic groups are distinct, non–amino acid atoms or molecular groupings that are permanently bound to their enzymes. An example is flavin adenine dinucleotide (FAD), which is bound to succinate dehydrogenase, an important enzyme in cellular respiration (see [Key Concept 9.3](#)).

Inorganic cofactors include ions such as copper, zinc, and iron that are permanently bound to certain enzymes. For example, the enzyme alcohol dehydrogenase contains the cofactor zinc.

A *coenzyme* is a nonprotein carbon-containing molecule that is required for the action of one or more enzymes. It is usually relatively small compared with the enzyme to which it binds.

A coenzyme moves from enzyme to enzyme, adding or removing chemical groups from the substrate. A coenzyme is like a substrate in that it does not permanently bind to the enzyme: it binds to the active site, changes chemically during the reaction, and then separates from the enzyme to participate in other reactions. There is actually no clear distinction between the functions of coenzymes and some substrates. For example, ATP and ADP have been described as coenzymes, even though they are really substrates that gain or lose phosphate groups during chemical reactions. The term “coenzyme” was coined before the functions of these molecules were fully understood. Biochemists continue to use the term, and for consistency with the field, we use it in this book.

The substrate concentration affects the reaction rate

For a reaction of the type $A \rightarrow B$, the rate of the uncatalyzed reaction is directly proportional to the concentration of A. The higher the concentration of substrate, the faster the rate of the reaction. The appropriate enzyme not only speeds up the reaction; it also changes the shape of a plot of rate versus substrate concentration ([Figure 8.13](#)). For a given concentration of enzyme, the rate of the enzyme-catalyzed reaction initially increases as the substrate concentration increases from zero, but then it levels off. At some point, further increases in the

substrate concentration do not significantly increase the reaction rate—the maximum rate has been reached.

Figure 8.13 Catalyzed Reactions Reach a Maximum Rate Because there is usually less enzyme than substrate present, the reaction rate levels off when the enzyme becomes saturated.

The concentration of an enzyme is usually much lower than that of its substrate (e.g., in cells expressing the enzyme sucrase, there are far more molecules of sucrose than of the enzyme). As more and more substrate molecules bind to the available enzyme molecules, there is a saturation phenomenon like the one that occurs in facilitated diffusion (see [Figure 6.12](#)). When all the enzyme molecules are bound with substrate molecules, the enzyme is working as fast as it can—at its maximum rate. Nothing is gained by adding more substrate, because no free enzyme molecules are left to act as catalysts. Under these conditions the active sites are said to be saturated.

The maximum rate of a catalyzed reaction can be used to measure how efficient the enzyme is. The turnover number is the maximum number of substrate molecules that one enzyme molecule can convert to product per unit of time. This number ranges from 1 molecule every 2 seconds for lysozyme to an amazing 40 million molecules per second for the liver enzyme catalase.

8.4 recap

Enzymes orient their substrates to bring together specific atoms so that bonds can form. An enzyme can participate in the reaction it catalyzes by temporarily changing shape or destabilizing the enzyme-substrate complex. Some enzymes require prosthetic groups, inorganic co-factors, or coenzymes in order to function.

learning outcomes

You should be able to:

- Give examples of mechanisms for enzyme catalysis.
- Describe coenzymes and cofactors and how they function.

- Predict changes in the rate of an enzyme-catalyzed reaction as factors in the reaction are varied.
-

1. The chemical composition of an enzyme before and after a catalyzed reaction is the same, but during the reaction an enzyme can change. How and why does this happen?
 2. Compare enzymes and coenzymes with regard to chemical structure and function.
 3. Plot reaction rate versus substrate concentration, and explain the shape of the curve.
-

You've seen in this section how individual enzymes work on their substrates. However, enzymes inside organisms don't operate in isolation—there may be thousands of different enzymes within a given cell. Let's see how all these different enzymes work together in a complex organism.

***connect the concepts** The number of molecules of a particular enzyme present in a cell at a given time is controlled in large part by the synthesis of that protein. See [Key Concept 16.1](#) for a discussion of the regulation of protein synthesis.

8.5 Enzyme Activities Can Be Regulated

The biochemical reactions in cells operate within metabolic pathways in which the product of one reaction is a reactant for the next. These pathways do not exist in isolation, but interact extensively, and each reaction in each pathway is catalyzed by a specific enzyme.

focus your learning

The cell carries out large numbers of metabolic reactions that are interconnected and regulated by the enzymes that catalyze them.

Small molecules can regulate enzyme activity by binding to and activating or inhibiting an enzyme.

Allosteric regulation results from the binding of regulator molecules to sites on an enzyme other than the active site.

Environmental factors such as pH and temperature affect enzyme activity.

Within a cell or organism, the presence and activity of enzymes determine the “flow” of chemicals through different metabolic pathways. The amount of enzyme activity, in turn, can be controlled in two ways:

- . *Regulation of gene expression.* The gene for an enzyme protein may be expressed more or less, resulting in more or fewer enzyme molecules in the cell. You learned in [Chapter 7](#) that some signal transduction pathways result in changes in gene expression, and that often the genes that are switched on or off encode enzymes.
- . *Regulation of enzyme activity.* The enzyme may change its shape to hide its active site from the substrate, or a regulator molecule may prevent the substrate from reaching the active site. Blocking the activity of a single enzyme can affect an entire metabolic pathway.

The flow of molecules through interacting metabolic pathways can be studied, but this process quickly becomes complicated, because each pathway influences the others. Computer algorithms are used to model these pathways and show how they mesh in an interdependent system ([Figure 8.14](#)). Such models can help predict what will happen if the concentration of one molecule or another is altered. This new field of biology is called [systems biology](#), and it has numerous applications.

Figure 8.14 Metabolic Pathways The complex interactions of metabolic pathways can be modeled by the tools of systems biology. In cells, the main elements controlling these pathways are enzymes.

systems biology The scientific study of an organism as an integrated and interacting system of genes, proteins, and biochemical reactions.

In this section we will investigate the roles of enzymes in organizing and regulating metabolic pathways. We will also examine how the environment—particularly temperature and pH—affects enzyme activity.

Activity 8.3 System Simulation www.Life11e.com/ac8.3

Enzymes can be regulated by inhibitors

Various chemical inhibitors can bind to enzymes, slowing down the rates of the reactions they catalyze. Some inhibitors occur naturally in cells; others are artificial. Naturally occurring inhibitors regulate metabolism; artificial ones can be used to treat disease, to kill pests, or to study how enzymes work. In some cases the inhibitor binds the enzyme irreversibly, and the enzyme becomes permanently inactivated. In other cases the inhibitor has reversible effects; it can separate from the enzyme, allowing the enzyme to function fully as before. The removal of a natural reversible inhibitor increases an enzyme's rate of catalysis.

IRREVERSIBLE INHIBITION

If an inhibitor covalently binds to certain side chains at the active site of an enzyme, it will permanently inactivate the enzyme by destroying its capacity to interact with its normal substrate. An example of an irreversible inhibitor is aspirin, which was described in the opening of this chapter. Aspirin (acetylsalicylic acid) binds to a target enzyme called cyclooxygenase (COX) near its active site. When it binds, aspirin releases its acetyl group ($-\text{CH}_2\text{CH}_3$) and this group of atoms is transferred to bond covalently to serine at its polar hydroxyl group ([Figure 8.15](#)). The group of atoms now “coating” serine sticks out into a channel in the protein and prevents the substrate, arachidonic acid, from reaching the active site. So prostaglandin is no longer produced and its stimulation of inflammation and pain are blocked. The elucidation of the mechanism of aspirin's action as an inhibitor of a pathway involved in inflammation was a landmark in modern pharmacology, the study of drugs (**Investigating Life: How Do Anti-Inflammatory Drugs Work as Enzyme Inhibitors?**).

Figure 8.15 Irreversible Inhibition Aspirin transfers an acetyl group, which covalently bonds to a serine amino acid near the active site of its target enzyme. This permanent change prevents the substrate from binding.

REVERSIBLE INHIBITION

In some cases an inhibitor is similar enough to a particular enzyme's natural substrate to bind non-covalently to its active site, yet different enough that the enzyme catalyzes no chemical reaction. While such a molecule is bound to the enzyme, the natural substrate cannot enter the active site and the enzyme is unable to function. Such a molecule is called a **competitive inhibitor** because it competes with the natural substrate for the active site (**Figure 8.16A and B**). In this case, the degree of inhibition depends on the relative concentrations of the substrate and the inhibitor: if the inhibitor concentration is higher, it is more likely to bind the active site of the enzyme than the substrate, and vice versa. The inhibition is reversible because if the concentration of substrate is increased or if the concentration of inhibitor is reduced, the substrate is more likely to bind, and the enzyme is active again.

competitive inhibitor A nonsubstrate that binds to the active site of an enzyme and thereby inhibits binding of its substrate. (Contrast with noncompetitive inhibitor.)

(A) Normal enzyme–substrate binding

Normal substrate binding to enzyme active site.

(B) Competitive inhibition

A competitive inhibitor binds to the active site, preventing substrate binding.

(C) Uncompetitive inhibition

An uncompetitive inhibitor binds to the enzyme–substrate complex, preventing release of products.

(D) Noncompetitive inhibition

A noncompetitive inhibitor binds at a site other than the active site, changing enzyme structure so that normal substrate binding cannot occur.

Figure 8.16 Reversible Inhibition

▶ Animation 8.2 Enzyme Catalysis www.Life11e.com/a8.1

An example of a competitive inhibitor is the drug methotrexate. An important coenzyme in the formation of purines (components of nucleic acids) is tetrahydrofolate, which is formed from dihydrofolate in a reaction catalyzed by dihydrofolate reductase (DHFR):

When cancer cells reproduce, they need to replicate their DNA, and so they need to produce purines. This makes DHFR an ideal target for an anticancer drug. A team led by Sidney Farber at Harvard Medical School first showed that an analog of dihydrofolate could treat leukemia. The drug used by Farber (aminopterin) has since been replaced by a similar analog, methotrexate:

experiment

Original Papers: Vane, J. R. 1971. Inhibition of prostaglandin synthesis as a mechanism of action of aspirin-like drugs. *Nature* 231: 232–235.

Smith, J. B. and A. L. Wells. 1971. Aspirin selectively inhibits prostaglandin production in human platelets. *Nature* 231: 235–238.

The opening story in this chapter describes how willow bark, the source of what became aspirin, is a centuries-old remedy for pain and inflammation. Until the late twentieth century, it was assumed that aspirin acted directly on the nervous system. Working at England's Royal College of Surgeons, a group led by John Vane showed that aspirin acts instead as an inhibitor of the enzymatic reaction that produces prostaglandin (PG), a fatty acid derivative important in inflammation.

HYPOTHESIS Aspirin acts as an anti-inflammatory drug by inhibiting an enzyme that catalyzes prostaglandin synthesis.

METHOD

RESULTS

CONCLUSION In both animal and human cells, aspirin blocks the synthesis of the pro-inflammatory molecule, prostaglandin, in test tube experiments.

work with the data

For his discovery of the mechanism by which aspirin relieves pain, John Vane was awarded the Nobel Prize and knighted by Queen Elizabeth II. Key to the experiments was the assumption that enzyme activity and mechanism are the same outside the organism as they are inside. In the lab, if given its substrate and the same set of environmental conditions as in the cytoplasm, an enzyme will catalyze production of its product.

QUESTIONS

- In the first set of experiments, lung tissue from guinea pigs was broken up to form a cell-free extract (homogenate). The substrate, arachidonic acid, was added to the extract, and after 30 min the amount of prostaglandin (PG) was measured. The results are shown in **Table A**. Plot PG synthesis versus aspirin concentration. What can you conclude?
- A similar set of experiments was performed on human platelets (membrane-bound cell fragments derived from white blood cells). These cells are known to produce PG by the same enzyme mechanism as lung tissue under certain environmental conditions. The results are shown in **Table B**. What can you conclude from these results and about the generalizability of your conclusion from Question 1?

Table A

Aspirin concentration (μg/mL)	PG synthesis (ng)
0	220
1	172
2	136
10	99
50	33
80	0

Table B

Aspirin concentration (μg/mL)	PG synthesis (ng)
0	53
0.01	48
0.1	35
1	18
10	7

- In a third set of experiments, platelets were isolated from human volunteers and their ability to make PG was measured (no aspirin present). Then these people were given a clinically effective dose of aspirin, and after a short period their platelets were isolated and PG synthesis measured (again, no aspirin in the test tube experiments). The results from three people are shown in **Table C**. How do these data either reinforce or refute your conclusion from Questions 1 and 2?

Table C

Individual	Prostaglandin synthesis (ng)	
	Before aspirin	After aspirin
1	160	16
2	108	5
3	103	20

A similar **work with the data** exercise may be assigned in **LaunchPad**.

This successful drug is used to treat inflammatory diseases such as psoriasis and rheumatoid arthritis, as well as cancer.

An **uncompetitive inhibitor** (**Figure 8.16C**) binds to the enzyme–substrate complex, preventing the complex from releasing products. Unlike competitive inhibition, uncompetitive inhibition cannot be overcome by adding more substrate.

uncompetitive inhibitor An enzyme inhibitor that binds to the enzyme-substrate complex.

A **noncompetitive inhibitor** binds to an unbound enzyme at a site distinct from the active site. Binding causes a change in the shape of the enzyme that alters its activity (**Figure 8.16D**). The active site may no longer bind the substrate, or if it does, the rate of product formation may be reduced. Like competitive inhibitors, noncompetitive inhibitors can become unbound, so their effects are reversible.

noncompetitive inhibitor A nonsubstrate that inhibits the activity of an enzyme by binding to a site other than its active site. (Contrast with competitive inhibitor.)

Allosteric enzymes are controlled via changes in shape

The change in enzyme shape that is due to noncompetitive inhibitor binding is an example of allostery (*allo*, “different,” + *stereos*, “shape”). **Allosteric regulation** occurs when an effector molecule binds to a site other than the active site of an enzyme, *inducing the enzyme to change its shape*. The change in shape alters the affinity of the active site for the substrate, and so the rate of the reaction is changed.

allosteric regulation (al lo steer' ik) [Gk. *allos*: other + *stereos*: structure] Regulation of the activity of a protein (usually an enzyme) by the binding of an effector molecule to a site other than the active site.

Often, an enzyme will exist in the cell in more than one possible shape (**Figure 8.17**):

Figure 8.17 Allosteric Regulation of Enzymes Active and inactive forms of an enzyme can be interconverted, depending on the binding of effector molecules at sites

other than the active site. Binding an inhibitor stabilizes the inactive form, and binding an activator stabilizes the active form.

Animation 8.1 Allosteric Regulation of Enzymes www.Life11e.com/a8.2

The *active form* of the enzyme has the proper shape for substrate binding.

The *inactive form* of the enzyme has a shape that cannot bind the substrate.

Other molecules, collectively referred to as effectors, can influence which form the enzyme takes:

Binding of an inhibitor to a site other than the active site can stabilize the inactive form of the enzyme, making it less likely to convert to the active form.

The active form can be stabilized by the binding of an activator to another site on the enzyme.

Like substrate binding, the binding of inhibitors and activators to their regulatory sites (also called allosteric sites) is highly specific. Most (but not all) enzymes that are allosterically regulated are proteins with quaternary structure; that is, they are made up of multiple polypeptide subunits. The polypeptide that has the active site is called the catalytic subunit. The allosteric sites are often located on different polypeptides, called the regulatory subunits (see [Figure 8.17](#)).

Some enzymes have multiple subunits containing active sites, and the binding of substrate to one of the active sites causes allosteric effects. When substrate binds to one subunit, there is a slight change in protein structure that influences the adjacent subunit. The slight change to the second subunit makes its active site more likely to bind to the substrate. So the reaction speeds up as the sites become sequentially activated.

As a result, an allosteric enzyme with multiple active sites and a nonallosteric enzyme with a single active site differ greatly in their reaction rates when the substrate concentration is low. Graphs of reaction rates plotted against substrate concentrations show this relationship. For a nonallosteric enzyme, the plot is hyperbolic:

The reaction rate first increases sharply with increasing substrate concentration, then tapers off to a constant maximum rate as the supply of enzyme becomes saturated.

For a multisubunit allosteric enzyme, the graph looks different, having a sigmoid (S-shaped) appearance:

At low substrate concentrations, the reaction rate increases only gradually as substrate concentration increases. After the substrate binds to the first active site of the enzyme (the slowly increasing part of the curve), there is a change in the enzyme's quaternary structure such that the other sites become more likely to bind substrate, so the reaction speeds up (the rapidly increasing part of the curve). Once all sites are saturated with substrate, the reaction rate reaches a plateau (the upper, flat part of the curve). Within a certain range, the reaction rate is extremely sensitive to relatively small changes in substrate concentration. In addition, allosteric enzymes are very sensitive to low concentrations of inhibitors. Because of this sensitivity, allosteric enzymes are important in regulating entire metabolic pathways.

Allosteric effects regulate many metabolic pathways

Metabolic pathways typically involve a starting material, various intermediate products, and an end product that is used for some purpose by the cell. In each pathway there are a number of reactions, each forming an intermediate product and each catalyzed by a different *enzyme. The first step in a pathway is called the commitment step, meaning that once this enzyme-catalyzed reaction occurs, the "ball is rolling," and the other reactions happen in sequence, leading to the end product. But what if the cell has no requirement for that product—for example, if that product is available from its environment in adequate amounts? It would be energetically wasteful for the cell to continue making something it does not need.

One way to avoid this problem is to shut down the metabolic pathway by having the final product inhibit the enzyme that catalyzes the commitment step ([Figure 8.18](#)). Often this inhibition occurs allosterically. When the end product is present at a high concentration, some of it binds to an allosteric site on the commitment step enzyme, thereby causing it to become inactive. Thus the final product acts as a noncompetitive inhibitor (described earlier in this section) of the first enzyme in the pathway. This mechanism is known as feedback inhibition or end-product inhibition. We will describe many other examples of such inhibition in later chapters.

(A) Feedback inhibition

(B) Gout

If the enzyme PRPP synthetase is genetically unable to bind purines for feedback inhibition, excess purines accumulate and lead to the formation of crystals in joints (gout).

Figure 8.18 Feedback Inhibition of Metabolic Pathways (A) The first reaction in a metabolic pathway is referred to as the commitment step. It is often catalyzed by an enzyme that can be allosterically inhibited by the end product of the pathway. The specific pathway shown here is the synthesis of purine nucleotides (ATP, GTP) from ribose 5-phosphate in humans. (B) Gout, an accumulation of crystals in joints caused by an excess of purines, can occur if there is a failure of feedback inhibition.

Many enzymes are regulated through reversible phosphorylation

Many enzymes involved in signal transduction are regulated via reversible phosphorylation (see [Figure 7.14A](#)). An enzyme can be activated by a protein kinase, which adds a phosphate from ATP to one or more specific amino acids. This results in a change in the shape of the enzyme, making it active. Such activation is reversible because another enzyme called a protein

phosphatase can catalyze the hydrolysis and removal of phosphate groups, so that the enzyme becomes inactive again. In addition to the enzymes involved in signal transduction, many other enzymes and proteins in the cell (such as ion channels) are regulated via reversible phosphorylation. Reflecting the important role of protein phosphorylation in cell functions, the human genome contains more than 500 protein kinase genes: about 2 percent of all the protein-coding genes we have.

Enzymes are affected by their environment

Enzymes enable cells to perform chemical reactions and carry out complex processes rapidly without using the extremes of temperature and pH employed by chemists in the laboratory. However, because of their three-dimensional structures and the chemistry of the side chains in their active sites, enzymes (and their substrates) are highly sensitive to changes in temperature and pH. In [Key Concept 3.2](#) we described the general effects of these environmental factors on proteins. Here we will examine their effects on enzyme function (which, of course, depends on enzyme structure and chemistry).

pH AFFECTS ENZYME ACTIVITY

The rates of most enzyme-catalyzed reactions depend on the pH of the solution in which they occur. While the water inside cells is generally at a neutral pH of 7, the presence of acids, bases, and buffers can alter this. Each enzyme is most active at a particular pH; its activity decreases as the solution is made more acidic or more basic than the ideal (optimal) pH ([Figure 8.19](#)). As an example, consider the human digestive system (see [Key Concept 50.3](#)). The pH inside the human stomach is highly acidic, around pH 1.5. However, many enzymes that hydrolyze macromolecules in the intestines, such as proteases, have pH optima in the neutral range. So when food enters the small intestine, a buffer (bicarbonate) is secreted into the intestine to raise the pH to 6.5. This allows the hydrolytic enzymes to be active and digest the food.

Figure 8.19 pH Affects Enzyme Activity An enzyme catalyzes its reaction at a maximum rate. The activity curve for each enzyme peaks at its optimal pH. For example, pepsin is active in the acidic environment of the stomach, whereas

chymotrypsin is active in the small intestine.

Q: Inside the cell, the pH of the cytoplasm is typically 7.2, but inside the lysosome the pH is 4.8. A protease, which catalyzes the hydrolysis of proteins, is active within the lysosome but is inactive in the cytoplasm. How can this occur?

An important factor in the effect of pH on enzyme function is ionization of the carboxyl, amino, and other groups on either the substrate or the enzyme. In neutral or basic solutions, carboxyl groups (—COOH) release H^+ to become negatively charged carboxylate groups (—COO^-). However, in neutral or acidic solutions, amino groups (—NH_2) accept H^+ to become positively charged —NH_3^+ groups (see the discussion of acids and bases in [Key Concept 2.4](#)). Thus in a neutral solution, an amino group is electrically attracted to a carboxyl group on another molecule or another part of the same molecule, because both groups are ionized and have opposite charges. If the pH changes, however, the ionization of these groups may change. For example, at a low pH (high H^+ concentration, such as the stomach contents where the enzyme pepsin is active), the excess H^+ may react with —COO^- to form —COOH . If this happens, the group is no longer negatively charged and can no longer interact with positively charged groups in the protein, so the folding of the protein may be altered. If such a change occurs at the active site of an enzyme, the enzyme may no longer be able to bind to its substrate.

TEMPERATURE AFFECTS ENZYME ACTIVITY

In general, warming increases the rate of a chemical reaction because a greater proportion of the reactant molecules have enough kinetic energy to provide the activation energy for the reaction. Enzyme-catalyzed reactions are no different ([Figure 8.20](#)). However, temperatures that are too high inactivate enzymes, because at high temperatures enzyme molecules vibrate and twist so rapidly that some of their noncovalent bonds break. When an enzyme's tertiary structure is changed by heat it loses its function. Some enzymes denature at temperatures only slightly above that of the human body, but a few are stable even at the boiling point (or freezing point) of water. All enzymes, however, have an optimal temperature for activity.

Figure 8.20 Temperature Affects Enzyme Activity Each enzyme is most active at a particular optimal temperature. At higher temperatures the enzyme becomes denatured and inactive; this explains why the activity curve falls off abruptly at temperatures above the optimum.

In general, enzymes adapted to warm temperatures do not denature at those temperatures, because their tertiary structures are held together largely by covalent bonds and disulfide bridges, instead of the more heat-sensitive weak chemical interactions. Most enzymes in humans are more stable at high temperatures than are those of the bacteria that infect us, so that a moderate fever tends to denature bacterial enzymes, but not our own.

8.5 recap

The rates of most enzyme-catalyzed reactions are affected by interacting molecules (such as inhibitors and activators) and by environmental factors (such as temperature and pH). Reversible phosphorylation is another important mechanism for regulating enzyme activity.

learning outcomes

You should be able to:

- Explain how metabolic pathways can shift in different directions.
- Distinguish between different types of inhibitors.
- Apply the concept of allosteric regulation to explain experimental results.

1. What is feedback inhibition? How might the reactions shown in [Figure 8.18A](#) fit into a systems diagram like the one shown in [Figure 8.14](#)?
2. Consider an enzyme that is subject to allosteric regulation. If a competitive inhibitor (not an allosteric inhibitor) is added to a solution containing such an enzyme, the ratio of enzyme molecules in the active form to those in the inactive form increases. Explain this observation.
3. In humans, hydrogen peroxide (H_2O_2) is a dangerous toxin produced as a by-product of several metabolic pathways. The accumulation of H_2O_2 is prevented by its conversion to harmless H_2O , a reaction catalyzed by the appropriately named enzyme catalase. Air pollutants can inhibit this enzyme and leave individuals susceptible to tissue damage by H_2O_2 . How would you investigate whether catalase has an allosteric or a nonallosteric mechanism and whether the pollutants are acting as competitive or noncompetitive inhibitors?

investigatinglife

How do anti-inflammatory drugs work as enzyme inhibitors?

Go into a drugstore or watch ads on TV, and it becomes obvious that there are many drugs that alleviate pain. Like aspirin, many of them target the prostaglandin pathway for inflammation. John Vane's research and later work showed that aspirin irreversibly inhibits the enzyme COX. But it turns out that there are two forms of COX, called COX-1 and COX-2, and there are several kinds of

prostaglandins. COX-1 catalyzes the production of protective prostaglandins that are involved with blood clotting (which is why people take aspirin to prevent future heart attacks due to blood clots) and the integrity of the lining of the stomach. COX-2 catalyzes production of prostaglandins involved with inflammation and associated pain. Aspirin inhibits both COX-1 and COX-2. So it is not surprising that people are advised to go easy on aspirin: it may block pain, but its use can lead to stomach upsets and an inability to clot blood after a wound. Knowledge of aspirin's limitations has led to a search for inhibitors of COX-2 only. Most of them are competitive inhibitors. How would this affect how often you need to take the drug? Look up one of these drugs and read the description of how it works.

Future directions

As details at the atomic level of the binding of enzymes to substrates are worked out, biologists use the data to try to predict which substrates might bind to which enzymes. An important consideration in binding is ΔG ; the less positive this parameter, the more likely binding will occur. Factors such as ionic attractions and van der Waals forces contribute to the ΔG of binding. These factors are also important in the binding of proteins to nonsubstrate molecules, including other proteins and RNA. Indeed, it is becoming apparent that in general a protein in the cell does not exist in isolation, but is bound to something(s) else. If the protein is an enzyme, its substrate binding must be its most preferred partner. Understanding all the possible molecular interactions will result in a deeper understanding of what really goes on at the chemical level inside the cell.

► 8.1 Physical Principles Underlie Biological Energy Transformations

- **Energy** is the capacity to do work. In a biological system, the usable energy is called **free energy (G)**. The unusable energy is **entropy (S)**, a measure of the disorder in the system.

energy The capacity to do work or move matter against an opposing force. The capacity to accomplish change in physical and chemical systems.

free energy (G) Energy that is available for doing useful work, after allowance has been made for the increase or decrease of disorder.

- **Potential energy** is the energy of state or position; it includes the energy stored in chemical bonds. **Kinetic energy** is the energy of motion; it is the type of energy that can do work.

potential energy Energy not doing work but with the potential to do so, such as the energy stored in chemical bonds. (Contrast with kinetic energy.)

kinetic energy (kuh-net' ik) [Gk. *kinetos*: moving] The energy associated with movement. (Contrast with potential energy.)

- The **laws of thermodynamics** apply to living organisms. The first law states that energy cannot be created or destroyed. The second law states that energy transformations decrease the amount of energy available to do work (free energy) and increase disorder.

Review Figure 8.2

laws of thermodynamics [Gk. *thermos*: heat + *dynamis*: power] Laws derived from studies of the physical properties of energy and the ways energy interacts with matter. (See also first law of thermodynamics, second law of thermodynamics.)

- The change in free energy (ΔG) of a reaction determines its **chemical equilibrium**, the point at which the forward and reverse reactions proceed at the same rate.

chemical equilibrium See equilibrium.

- An **exergonic** reaction releases free energy and has a negative ΔG . An **endergonic** reaction consumes or requires free energy and has a positive ΔG . Endergonic reactions proceed only if free energy is provided. **Review Figure 8.3**

exergonic A chemical reaction in which the products of the reaction have lower free energy than the reactants, resulting in a release of free energy. (Contrast with endergonic.)

endergonic A chemical reaction in which the products have higher free energy than the

reactants, thereby requiring free energy input to occur. (Contrast with exergonic.)

- **Metabolism** is the sum of all the biochemical (metabolic) reactions occurring in an organism at a given time. **Catabolic reactions** are associated with the breakdown of complex molecules and release energy (are exergonic). **Anabolic reactions** build complexity in the cell and are endergonic.

metabolism (meh tab' a lizm) [Gk. *metabole*: change] The sum total of the chemical reactions that occur in an organism, or some subset of that total (as in respiratory metabolism).

catabolic reaction (kat uh bah' lik) [Gk. *kata*: to break down + *ballein*: to throw] A synthetic reaction in which complex molecules are broken down into simpler ones and energy is released. (Contrast with anabolic reaction.)

anabolic reaction (an uh bah' lik) [Gk. *ana*: upward + *ballein*: to throw] A synthetic reaction in which simple molecules are linked to form more complex ones; requires an input of energy and captures it in the chemical bonds that are formed. (Contrast with catabolic reaction.)

▶ 8.2 ATP Plays a Key Role in Biochemical Energetics

- Adenosine triphosphate (ATP) serves as an energy currency in cells. Hydrolysis of ATP releases a relatively large amount of free energy.
- The ATP cycle couples exergonic and endergonic reactions, harvesting free energy from exergonic reactions, and providing free energy for endergonic reactions. **!!Review Figure 8.6, Activity 8.1**

▶ 8.3 Enzymes Speed Up Biochemical Transformations

- The rate of a chemical reaction is independent of ΔG but is determined by the energy barrier. **Review Focus: Key Figure 8.8**
- Enzymes are protein catalysts that affect the rates of biological reactions by lowering the energy barrier, supplying the **activation energy** (E_a) needed to initiate reactions. **!!Review Figure 8.10, Activity 8.2**

activation energy (E_a) The energy barrier that blocks the tendency for a chemical reaction to occur.

- A **substrate** binds to the enzyme's active site—the site of catalysis—forming an **enzyme–substrate complex** (ES). Enzymes are highly specific for their substrates. **Review Figure 8.9**

substrate (sub' strayte) (1) The molecule or molecules on which an enzyme exerts catalytic action. (2) The base material on which a sessile organism lives.

enzyme–substrate complex (ES) An intermediate in an enzyme-catalyzed reaction; consists of the enzyme bound to its substrate(s).

- Enzymes can be classified as to the type of chemical reaction catalyzed.

▶ 8.4 Enzymes Bring Substrates Together so Reactions Readily Occur

- At the active site, a substrate can be oriented correctly, chemically modified, or strained. Any of these factors can induce the substrate to readily reach its **transition state**,

allowing the reaction to proceed. **Review** [Figure 8.11](#)

transition state In an enzyme-catalyzed reaction, the reactive condition of the substrate after there has been sufficient input of energy (activation energy) to initiate the reaction.

- Binding substrate causes many enzymes to change shape, exposing their active site(s) and allowing catalysis. The change in enzyme shape caused by substrate binding is known as **induced fit**. **Review** [Figure 8.12](#)

induced fit A change in the shape of an enzyme caused by binding to its substrate that exposes the active site of the enzyme.

- Some enzymes require other substances, known as cofactors, to carry out catalysis. Prosthetic groups are permanently bound to enzymes; coenzymes are not. A coenzyme can be considered a substrate, as it is changed by the reaction and then released from the enzyme.
- Substrate concentration affects the rate of an enzyme-catalyzed reaction. **Review** [Figure 8.13](#)

▶ 8.5 Enzyme Activities Can Be Regulated

- metabolism is organized into pathways in which the product of one reaction is a reactant for the next reaction. Each reaction in the pathway is catalyzed by a different enzyme. **!!Review** [Activity 8.3](#)
- Enzyme activity is subject to regulation. Some inhibitors bind irreversibly to enzymes. Others bind reversibly. **!!Review** [Figures 8.15, 8.16](#), [Animation 8.1](#)
- An allosteric effector binds to a site other than the active site and stabilizes the active or inactive form of an enzyme. **!!Review** [Figure 8.17](#), [Animation 8.2](#)
- The end product of a metabolic pathway may inhibit an enzyme that catalyzes the commitment step of that pathway. **Review** [Figure 8.18](#)
- Reversible phosphorylation is an important mechanism for regulating enzyme activity.
- Enzymes are sensitive to their environments. Both pH and temperature affect enzyme activity. **!!Review** [Figures 8.19, 8.20](#)

Original Papers: McElroy, W. D. 1947. The energy source for bioluminescence in an isolated system. *Proceedings of the National Academy of Sciences USA* 33: 342–345.

McElroy, W. D. and B. L. Strehler. 1954. Bioluminescence. *Bacteriological Reviews* 18: 177–194.

Thompson, J. F. et al. 1997. Mutation of a protease-sensitive region in firefly luciferase alters light emission properties. *Journal of Biological Chemistry* 272: 18766–18771.

Many people enjoy watching and catching fireflies on warm summer nights, but the attraction isn't mutual; a firefly's primary goal is to find a mate. Male and female fireflies use specific patterns of light flashes to attract one another. The flashes are emitted from the firefly lantern, an organ located in the firefly abdomen.

Light is a form of energy, which means that fireflies must divert some of their energy to produce light flashes. Researchers used a biochemical approach to learn how this is done. When the lanterns of fireflies are ground up and extracted with water, the extract briefly produces an intense light, which then fades away. If ATP is added to the extract, light is again emitted, and again, it fades. The graph below shows the duration of light emission as a function of the amount of ATP added. When anaerobic conditions were used, no light was observed.

Through additional investigations, the researchers discovered that a compound called luciferin was responsible for the light emission as luciferin underwent a chemical reaction. The researchers purified an enzyme from extracts of firefly lanterns. The enzyme catalyzes the

reaction in which luciferin emits light. In further studies, amounts of luciferin, ATP, and magnesium ion, Mg^{2+} , were found to give the maximum light intensity (100%) when mixed with a fixed amount of enzyme. The table below shows how the relative light intensity was affected when variables were changed.

Variable	Light intensity (%)
No enzyme	0
Enzyme heated before being added	0
No magnesium ion	4
1 mM magnesium ion	70
10 mM magnesium ion	100
pH 6.5	30
pH 7.6	100
pH 9.0	64

Questions

1. Based on the information given, what set of molecules is necessary for the production of light by firefly lanterns, and what role does each molecule serve?
2. Explain how energy taken in by the firefly from its environment is made available for the production of light in a firefly lantern.
3. Additional research has shown that an activated intermediate forms at the active site of the enzyme as luciferin reacts. This intermediate consists of luciferin covalently bonded to adenosine monophosphate (AMP). Still at the active site, this intermediate then reacts with oxygen to make an oxidized form of luciferin with the emission of light. The diagram below shows these steps. Redraw the diagram, adding steps to illustrate how coupling reactions could be involved to provide the energy needed for light emission.

1. What evidence is there that the enzyme is sensitive to environmental factors? Suggest possible reasons why this enzyme responds as it does to these factors.
2. Some studies have shown that the enzyme undergoes a shape change upon binding ATP and luciferin. This change makes it impossible for a molecule of water to fit into the active site along with the substrates. What property of an enzyme does this represent, and how does this property help this particular enzyme carry out its role in catalysis?

A Weighty Matter

With 17 percent of children and 35 percent of adults in the United States now described as obese, physicians have declared an “obesity epidemic.” Dramatic increases in diseases associated with obesity—among them diabetes, heart disease, and cancer—have understandably alarmed the medical establishment.

While nutritional science has shown that not all foods affect all people in the same ways, in most cases the significant excess body weight of obese people can be prevented or reduced if they eat less and exercise more. It is a matter of energy: if we eat more energy-yielding molecules than we need to build our bodies and to fuel activities such as brain functions and physical activity, we will store the unneeded energy as fat. There is an evolutionary advantage in storing fat: the energy in the C—C and C—H bonds in fat can be used later when food is scarce. But excess fat has adverse consequences.

Not all fat (adipose) tissues are the same. White adipose tissue (sometimes referred to simply as white fat”) is used primarily to store energy. Brown adipose tissue has high concentrations of mitochondria, which have iron-containing pigments. When energy-rich molecules in brown fat are catabolized, the stored energy is released not as chemical energy but as heat. The cells in brown fat make a protein called UCP1 (uncoupling protein 1) that inserts into the inner membranes of mitochondria, making them permeable to protons (H^+). The general impermeability of these membranes to H^+ is key to coupling the catabolism of molecules such as fats to the release of their stored energy in chemical form (to make ATP). If the membranes become permeable to H^+ , this coupling is lost and the stored energy is released as heat.

Human infants are born with a great deal of brown fat in their back and shoulders. Because infants have a high surface area-to-volume ratio, they tend to lose a lot of heat. One way they keep warm is to produce heat in their brown fat tissues. As a child grows up, the brown fat content of the body is reduced. Adults have mostly white fat, which has less UCP1 and generates less heat when the fat is catabolized. But biologists recently found brown fat in adults, and its significance is gaining increasing attention.

How are mitochondria related to obesity?

9.1 Cells Harvest Chemical Energy from Glucose Oxidation

Energy is stored in the covalent bonds of fuels, and it can be released and transformed. You will recall from [Chapter 8](#) that energy transformations can involve light, heat, chemical, mechanical, and electrical energy. For example, when you burn wood, it releases a great deal of its energy as heat and light. In cells, molecules used as fuels release chemical energy that is used to make ATP, which in turn drives endergonic reactions. Photosynthetic cells and organisms use energy from sunlight to synthesize their own fuels, as we will describe in [Chapter 10](#). In nonphotosynthetic cells, the most common chemical fuel is the monosaccharide glucose. Other molecules, including other carbohydrates, fats, and proteins, can supply energy to the whole organism. However, to release their energy they must be converted into glucose or intermediate compounds that can enter into the various pathways of glucose metabolism.

focus your learning

Basic principles of chemistry govern metabolic pathways in cells.

Energy is transferred as electrons move from one molecule to another via an oxidation-reduction reaction.

Electron carrier molecules function as coenzymes to pick up or donate electrons during biological redox reactions.

How do cells obtain energy from glucose?

Cells obtain ***energy** from glucose by the chemical process of oxidation, which is carried out through a series of metabolic pathways. As you read this chapter, keep in mind five principles that govern metabolic pathways:

- . A complex chemical transformation occurs in a series of separate reactions that form a metabolic pathway.
- . Each reaction is catalyzed by a specific enzyme.
- . Many metabolic pathways are similar in all organisms, from bacteria to humans.
- . In eukaryotes, many metabolic pathways are compartmentalized, with certain reactions occurring inside specific organelles, or even specific regions of an organelle.
- . Some key enzymes in each metabolic pathway can be inhibited or activated to alter the rate of the pathway.

As you saw in [Key Concept 2.3](#), the familiar process of combustion (burning) is similar to the chemical processes that release energy in cells. If glucose is burned in a flame or is in a typical cell, it reacts with oxygen gas (O₂), forming carbon dioxide and water and releasing energy in the form of heat. The balanced equation for the complete reaction is

This is an oxidation–reduction reaction (more on this shortly), in which glucose loses electrons

(becomes oxidized) and oxygen gains them (becomes reduced). The large standard free energy change (ΔG) is negative, indicating that the overall conversion is highly exergonic and can drive the endergonic formation of a lot of ATP from ADP and phosphate:

The oxidation of glucose when you heat it in the lab happens all at once. But in cells, glucose catabolism happens in many steps in a pathway. Each step is catalyzed by an enzyme, and the process is compartmentalized. Unlike combustion, glucose catabolism is tightly regulated and occurs at temperatures compatible with life.

Three catabolic processes harvest the energy in the chemical bonds of glucose: glycolysis, cellular respiration, and fermentation ([Figure 9.1](#)). All three processes involve pathways made up of many distinct chemical reactions.

Figure 9.1 Energy for Life Many prokaryotes and all eukaryotes obtain their energy from the food compounds produced by photosynthesis. They often convert these compounds into glucose, which they metabolize to trap energy in ATP.

- [Glycolysis](#) begins glucose catabolism. Through a series of chemical rearrangements, glucose is converted to two molecules of the three-carbon product [pyruvate](#), and a small amount of energy is captured in usable forms. Glycolysis is an [anaerobic](#) process because it does not

require O₂.

- **Cellular respiration** uses O₂ from the environment and thus is **aerobic**. Each pyruvate molecule is completely converted into three molecules of CO₂ through a set of catabolic pathways including pyruvate oxidation, the citric acid cycle, and an electron transport system (the respiratory chain). In the process, a great deal of the energy stored in the covalent bonds of pyruvate is captured to form ATP.
- **Fermentation** does not involve O₂ (it is anaerobic). With the exception of many microorganisms, fermentation converts pyruvate into lactic acid or ethyl alcohol (ethanol), both of which are still relatively energy-rich molecules. Because the breakdown of glucose is incomplete, much less energy is released when glycolysis is coupled to fermentation than when it is coupled to cellular respiration.

glycolysis (gly kol' li sis) [Gk. *gleukos*: sugar + *lysis*: break apart] The enzymatic breakdown of glucose to pyruvic acid.

pyruvate The ionized form of pyruvic acid, a three-carbon acid; the end product of glycolysis and the raw material for the citric acid cycle.

anaerobic (an ur row' bic) [Gk. *an*: not + *aer*: air + *bios*: life] Occurring without the use of molecular oxygen, O₂. (Contrast with aerobic.)

cellular respiration The catabolic pathways by which electrons are removed from various molecules and passed through intermediate electron carriers to O₂, generating H₂O and releasing energy.

aerobic (air oh' bic) [Gk. *aer*: air + *bios*: life] In the presence of oxygen; requiring or using oxygen (as in **aerobic metabolism**). (Contrast with anaerobic.)

fermentation (fur men tay' shun) [L. *fermentum*: yeast] The anaerobic degradation of a substance such as glucose to smaller molecules such as lactic acid or alcohol with the extraction of energy.

Redox reactions transfer electrons and energy

As you saw in [Key Concept 8.2](#), the addition of a phosphate group to ADP to make ATP is an endergonic reaction (see [Figure 8.6](#)). It is achieved by coupling an exergonic reaction to ATP production: the energy released in the exergonic reaction is used to drive ATP synthesis. Electrons are transferred in the exergonic reaction. A reaction in which one substance transfers one or more electrons to another substance is called an **oxidation-reduction**, or **redox**, reaction.

oxidation–reduction (redox) reaction A reaction in which one substance transfers one or more electrons to another substance. (See oxidation, reduction.)

Reduction is the gain of one or more electrons by an atom, ion, or molecule.

Oxidation is the loss of one or more electrons.

reduction Gain of electrons by a chemical reactant. (Contrast with oxidation.)

oxidation (ox i day' shun) Relative loss of electrons in a chemical reaction; either outright removal to form an ion, or the sharing of electrons with substances having a greater affinity

for them, such as oxygen. Most oxidations, including biological ones, are associated with the liberation of energy. (Contrast with reduction.)

Oxidation and reduction *always occur together*: as one chemical is oxidized, the electrons it loses are transferred to another chemical, reducing it. In a redox reaction, we call the reactant that becomes reduced an oxidizing agent and the one that becomes oxidized a reducing agent:

In the metabolism of glucose:

Glucose is the reducing agent (electron donor).

O_2 is the oxidizing agent (electron acceptor).

Although oxidation and reduction are always defined in terms of electrons, it is often simpler to think in terms of the gain or loss of hydrogen atoms. The transfer of electrons is often associated with the transfer of hydrogen ions (a H atom contains $H^+ + e^-$). So when a molecule loses hydrogen atoms, it becomes oxidized.

The more reduced a molecule is, the more energy is stored in its covalent bonds ([Figure 9.2](#)). In a redox reaction, some energy is transferred from the reducing agent to the reduced product. The rest remains in the reducing agent or is lost to entropy. As you will see, some of the key reactions of glycolysis and cellular respiration are highly exergonic redox reactions.

Figure 9.2 Oxidation, Reduction, and Energy The more oxidized a carbon atom in a molecule is, the less its stored free energy.

The coenzyme NAD^+ is a key electron carrier in redox reactions

The ***coenzyme** nicotinamide adenine dinucleotide (NAD^+) acts as an electron carrier in redox reactions. Note the flow of electrons along the blue lines below:

As you can see, NAD^+ exists in two chemically distinct forms, one oxidized (NAD^+) and the other reduced (NADH) (**Focus: Key Figure 9.3**). Both forms participate in redox reactions. The reduction reaction

focus: key figure

Figure 9.3 NAD^+/NADH Is an Electron Carrier in Redox Reactions NAD^+ is an important electron acceptor in redox reactions, and thus its reduced form, NADH , is

an important energy intermediary in cells. Most of the molecule (left) remains unchanged by the redox reaction.

Q: Where does the “H” in red come from when NAD is reduced?

is actually the transfer of a proton (the hydrogen ion, H^+) and two electrons, which are released by the accompanying oxidization reaction.

The electrons do not remain with the coenzyme. Oxygen is highly electronegative and readily accepts electrons from NADH. The oxidation of NADH by O_2 (which occurs in several steps)

is exergonic, with a standard free energy change at pH 7 (ΔG°) of -52.4 kcal/mol (-219 kJ/mol). Note that the oxidizing agent appears here as “ $\frac{1}{2} \text{O}_2$ ” instead of “O.” This notation emphasizes that it is molecular oxygen, O_2 , that acts as the oxidizing agent.

Just as ATP can be thought of as a package of 7.3 kcal/mol (30.5 kJ/mol) of free energy, NADH can be thought of as a larger package of free energy (52.4 kcal/mol ; see above). NAD^+ is a common electron carrier in cells, but not the only one. Another carrier, flavin adenine dinucleotide (FAD), also transfers electrons during glucose metabolism.

An overview: Harvesting energy from glucose

Both eukaryotic and prokaryotic cells can harvest energy from glucose using different combinations of the following metabolic pathways:

Under aerobic conditions, when O_2 is available as the final electron acceptor, four pathways operate ([Figure 9.4A](#)). Glycolysis is followed by the three pathways of cellular respiration: pyruvate oxidation, the citric acid cycle (also called the Krebs cycle or the tricarboxylic acid cycle), and electron transport/ATP synthesis (also called oxidative phosphorylation).

(A) Glycolysis and cellular respiration

(B) Glycolysis and fermentation

Figure 9.4 Energy-Yielding Metabolic Pathways Energy-yielding reactions can be grouped into five metabolic pathways: glycolysis, pyruvate oxidation, the citric acid cycle, the respiratory chain/ATP synthesis, and fermentation. (A) The three lower pathways occur only in the presence of O₂ and are collectively referred to as cellular respiration. (B) When O₂ is unavailable, glycolysis is followed by fermentation.

Activity 9.1 **Glycolysis and Fermentation** www.Life11e.com/ac9.1

In eukaryotes and many prokaryotes, pyruvate oxidation, the citric acid cycle, and oxidative phosphorylation do not function under anaerobic conditions. The pyruvate produced by glycolysis is further metabolized by fermentation ([Figure 9.4B](#)). Some prokaryotes, however, are able to harvest energy in pathways involving oxidative phosphorylation even in the absence of oxygen (anaerobic respiration; see [Key Concept 9.3](#)).

The five pathways shown in [Figure 9.4](#) occur in different locations in the cell ([Table 9.1](#)).

Eukaryotes	Prokaryotes
In cytoplasm	In cytoplasm

Inside mitochondrion	On cell membrane
Matrix	Pyruvate oxidation
Citric acid cycle	Respiratory chain
Pyruvate oxidation	
Inner membrane	
Respiratory chain	

 Activity 9.2 **Energy Pathways in Cells** www.Life11e.com/ac9.2

9.1 recap

The free energy released from the oxidation of glucose is trapped in the form of ATP. In many prokaryotes and all eukaryotes, five major pathways combine in different ways to produce ATP, which supplies the energy for myriad other reactions in living cells.

learning outcomes

You should be able to:

- Describe the principles of chemistry that govern metabolic pathways in cells.
- Identify the change in energy that occurs during an oxidation-reduction reaction.
- Describe the roles of electron acceptors and donors in biological redox reactions.
- Analyze biological redox reactions to identify the oxidizing and reducing agents involved.

1. What principles govern metabolic pathways in cells?
2. What are the roles of NAD^+ and O_2 with respect to electrons in a redox reaction?
3. The following reaction occurs in the citric acid cycle:

Answer each of the following questions, and explain your answers:

- a. Is this reaction an oxidation or a reduction?

- b. Is the reaction exergonic or endergonic?
- c. What kind of coenzyme does this reaction require?

Now that you have an overview of the metabolic pathways that harvest energy from glucose, let's take a closer look at the three pathways involved in aerobic glucose catabolism: glycolysis, pyruvate oxidation, and the citric acid cycle.

***connect the concepts** The principles of energy transformations in living and nonliving systems are discussed in [Key Concept 8.1](#).

***connect the concepts** [Key Concept 8.4](#) describes the role of coenzymes, small molecules that assist in enzyme-catalyzed reactions. ADP acts as a coenzyme when it picks up energy released in an exergonic reaction and packages it to form ATP.

9.2 In the Presence of Oxygen, Glucose Is Fully Oxidized

The aerobic pathways of glucose catabolism oxidize glucose completely to CO_2 and H_2O . Initially, the glycolysis reactions convert the six-carbon glucose molecule to two three-carbon pyruvate molecules ([Figure 9.5](#)). Pyruvate is then converted to CO_2 in a second series of reactions beginning with pyruvate oxidation and followed by the citric acid cycle. In addition to generating CO_2 , the oxidation events are coupled with the reduction of electron carriers, mostly NAD^+ .

One molecule of glucose

Fructose 1,6-bisphosphate

Two molecules of glyceraldehyde 3-phosphate

Two molecules of pyruvate

Figure 9.5 Glycolysis Converts Glucose into Pyruvate Glucose is converted to pyruvate in ten enzyme-catalyzed steps. Along the way, two ATP are used (Steps 1 and 3), two NAD^+ are reduced to two NADH (Step 6), and four ATP are produced (Steps 7 and 10).

focus your learning

Glucose is partially oxidized to pyruvate during glycolysis.

The generation of acetyl coenzyme A by pyruvate oxidation enables the entry of carbon from glucose into the citric acid cycle for further oxidation.

A large amount of energy is captured in electron carriers and in GTP as acetyl CoA is fully oxidized during the citric acid cycle.

We will begin our consideration of the catabolism of glucose with a closer look at glycolysis.

In the glycolysis pathway, glucose is partially oxidized

Glycolysis takes place in the cytoplasm and involves ten enzyme-catalyzed reactions. During glycolysis, some of the covalent bonds between carbon and hydrogen atoms in the glucose molecule are oxidized, releasing some of the stored energy. The products are two molecules of pyruvate (pyruvic acid), two molecules of ATP, and two molecules of NADH. Glycolysis can be divided into two stages: the initial energy-investing reactions that consume ATP, and the energy-harvesting reactions that produce ATP and NADH (see [Figure 9.5](#)).

To help you understand the process without getting into extensive detail, we will focus on two consecutive reactions in this pathway (Steps 6 and 7 in [Figure 9.5](#)).

Steps 6 and 7 are examples of two types of reactions that occur repeatedly in glycolysis and in many other metabolic pathways:

- **Oxidation–reduction:** The first reaction is exergonic—more than 50 kcal/mol of energy are released in the oxidation of glyceraldehyde 3-phosphate. (Look at the bottom carbon atom, where an H is replaced by an O.) The energy is trapped via the reduction of NAD^+ to NADH.
- **Substrate-level phosphorylation:** The second reaction in this series is also exergonic, but in this case less energy is released, sufficient to transfer a phosphate directly from the substrate to ADP, forming ATP.

The end product of glycolysis, pyruvate, is somewhat more oxidized than glucose. In the presence of O_2 , further oxidation can occur. In prokaryotes these subsequent reactions take place in the cytoplasm, but in eukaryotes they take place in the mitochondrial matrix.

To summarize:

The initial steps of glycolysis use the energy of hydrolysis of two ATP molecules per glucose molecule.

The remaining steps produce four ATP molecules per glucose molecule, so the net production of ATP is two molecules.

Glycolysis produces two molecules of NADH.

If O_2 is present, glycolysis is followed by the three stages of cellular respiration: pyruvate oxidation, the citric acid cycle, and the respiratory chain/ATP synthesis.

Pyruvate oxidation links glycolysis and the citric acid cycle

In eukaryotes, pyruvate is transported into the mitochondrial matrix (see [Figure 5.11](#)), where the next step in the aerobic catabolism of glucose occurs. This step involves the oxidation of pyruvate to a two-carbon acetate molecule and CO_2 . The acetate is then bound to coenzyme A to form [acetyl coenzyme A \(acetyl CoA\)](#); CoA is used in various biochemical reactions as a carrier of the acetyl group ($H_3C-C=O$).

acetyl coenzyme A (acetyl CoA) A compound that reacts with oxaloacetate to produce citrate at the beginning of the citric acid cycle; a key metabolic intermediate in the formation of many compounds.

Pyruvate is the link between glycolysis and further oxidative reactions (see [Figure 9.4](#)).

The formation of acetyl CoA is a multistep reaction catalyzed by the pyruvate dehydrogenase complex, which contains 60 individual proteins and 5 different coenzymes. The overall reaction is exergonic, in which one molecule of NAD^+ is reduced to NADH. However, the main role of acetyl CoA is to donate its acetyl group to the four-carbon compound oxaloacetate, forming the six-carbon molecule citrate. This initiates the citric acid cycle, one of life's most important energy-harvesting pathways.

The citric acid cycle completes the oxidation of glucose to CO_2

Acetyl CoA is the starting point for the citric acid cycle. This pathway of eight reactions completely oxidizes the two-carbon acetyl group to two molecules of CO_2 . The free energy released from these reactions is captured by GDP (guanosine diphosphate) and the electron carriers NAD^+ and FAD ([Figure 9.6](#)). (Remember from [Key Concept 7.2](#) that GDP is a nucleoside diphosphate like ADP.) This is a cycle because the starting material, oxaloacetate, is regenerated in the last step and is ready to accept another acetate group from acetyl CoA. The citric acid cycle operates twice for each glucose molecule that enters glycolysis (once for each pyruvate that enters the mitochondrion).

Figure 9.6 The Citric Acid Cycle The citric acid cycle has eight steps; in the last step, the starting material acceptor, oxaloacetate, is regenerated. Energy is released and captured by reducing NAD⁺ or FAD, or by producing GTP. "6C," "5C," and so on indicate the number of carbon atoms in each intermediate in the cycle.

 Activity 9.3 The Citric Acid Cycle www.Life11e.com/ac9.3

Let's focus on the final reaction of the cycle (Step 8 in [Figure 9.6](#)), as an example of the kind of reaction that occurs:

This oxidation reaction (see the carbon atom highlighted in blue) is exergonic, and the released energy is trapped by NAD^+ , forming NADH . With four such reactions (the FADH_2 produced in Step 6 is a reduced coenzyme similar to NADH), the citric acid cycle harvests a great deal of chemical energy from the oxidation of acetyl CoA.

To summarize:

The inputs to the citric acid cycle are acetate (in the form of acetyl CoA), water, GDP, and the oxidized electron carriers NAD^+ and FAD.

The outputs are carbon dioxide, reduced electron carriers (NADH and FADH_2), and a small amount of GTP. The energy in the terminal phosphate of GTP is transferred to ATP:

Thus the citric acid cycle releases two carbons as CO_2 and produces four reduced electron carrier molecules.

Overall, for each molecule of glucose that is oxidized, two molecules of pyruvate are produced during glycolysis, and after oxidation these feed two turns of the citric acid cycle. So the oxidation of one glucose molecule yields:

Six CO_2

Ten NADH (two in glycolysis, two in pyruvate oxidation, and six in the citric acid cycle)

Two FADH_2

Four ATP

Pyruvate oxidation and the citric acid cycle are regulated by the concentrations of starting materials

You have now seen that pyruvate, a three-carbon molecule, is completely oxidized to CO_2 by pyruvate dehydrogenase and the citric acid cycle. For the cycle to continue, the starting molecules—acetyl CoA and oxidized electron carriers—must all be replenished. The electron carriers are reduced during the citric acid cycle and in Step 6 of glycolysis (see [Figure 9.5](#)), and they must be reoxidized:

These oxidation reactions are coupled to reactions in which other molecules get reduced. When it is present, O_2 is the molecule that eventually accepts these electrons, and it is reduced to form H_2O .

9.2 recap

The oxidation of glucose in the presence of O₂ involves glycolysis, pyruvate oxidation, and the citric acid cycle. In glycolysis, glucose is converted to pyruvate with some energy capture. Pyruvate is oxidized first to acetyl CoA by pyruvate dehydrogenase, then completely to CO₂ by the citric acid cycle, releasing energy that is captured in the form of reduced electron carriers.

learning outcomes

You should be able to:

- Describe the energy inputs and outputs of glycolysis.
- Explain how pyruvate oxidation connects the transformations of glycolysis and the citric acid cycle.
- Compare and contrast glycolysis and the citric acid cycle.

1. What is the net energy yield of glycolysis in terms of energy in ATP and reduced coenzymes invested and energy harvested?
2. What role does pyruvate oxidation play in relation to the citric acid cycle?
3. How is the citric acid cycle a “cycle” but glycolysis is not?

Pyruvate oxidation and the citric acid cycle cannot continue operating unless O₂ is available to receive electrons during the reoxidation of reduced electron carriers. However, these electrons are not passed directly to O₂, as you will learn next.

9.3 Oxidative Phosphorylation Forms ATP

In the presence of O₂, [oxidative phosphorylation](#) is a process of ATP synthesis resulting from the reoxidation of electron carriers in the presence of O₂. In this section we describe oxidative phosphorylation as it occurs in mitochondria, but the same process occurs in prokaryotes (see [Table 9.1](#)).

oxidative phosphorylation ATP formation in the mitochondrion, associated with flow of electrons through the respiratory chain.

focus your learning

Chemiosmosis converts the potential energy of a proton concentration gradient to chemical energy in ATP.

Experimental results demonstrated the relationship between a proton gradient across a membrane and ATP synthesis

What are the steps in oxidative phosphorylation?

Two components of the process can be distinguished:

- . *Electron transport.* The electrons from NADH and FADH₂ pass through the [respiratory chain](#), a series of membrane-associated electron carriers. The flow of electrons along this pathway results in the active transport of protons out of the mitochondrial matrix and across the inner mitochondrial membrane, creating a proton concentration gradient.
- . *Chemiosmosis.* The protons diffuse back into the mitochondrial matrix through a channel protein, [ATP synthase](#), which couples this diffusion to the synthesis of ATP. As we mentioned in the chapter opening, the inner mitochondrial membrane is normally impermeable to protons, so the only way for them to follow their concentration gradient is through the channel.

respiratory chain The terminal reactions of cellular respiration, in which electrons are passed from NAD or FAD, through a series of intermediate carriers, to molecular oxygen, with the concomitant production of ATP.

ATP synthase An integral membrane protein that couples the transport of protons with the formation of ATP.

Before we proceed with the details of these pathways, let's consider an important question: Why should the respiratory chain be such a complex process? Why don't cells use the following single step?

The answer is that this reaction would simply release too much energy to be efficiently trapped to make ATP. Oxidizing NADH to NAD⁺ is extremely exergonic—doing it in one step would be

like setting off a stick of dynamite in the cell. There is no biochemical way to harvest that burst of energy efficiently and put it to physiological use (that is no single metabolic reaction is so endergonic as to consume a significant fraction of that energy in a single step). To control the release of energy during the oxidation of glucose, cells have evolved a lengthy respiratory chain: a series of reactions, each of which releases a small amount of energy, one step at a time.

The respiratory chain transfers electrons and protons, and releases energy

The respiratory chain is located in the inner mitochondrial membrane. Because of the extensive folding of the membrane, there is more room for the proteins involved in the chain than there would be in a membrane with less surface area. There are several interacting components, including large integral proteins, a small peripheral protein, and a small lipid molecule. [Figure 9.7](#) shows a plot of the free energy released as electrons are passed between the carriers.

Figure 9.7 The Oxidation of NADH and FADH₂ in the Respiratory Chain Electrons from NADH and FADH₂ are passed along the respiratory chain, a series of protein complexes in the inner mitochondrial membrane containing electron carriers and

enzymes. The carriers gain free energy when they become reduced and release free energy when they are oxidized. This illustration shows the standard free energy changes along the respiratory chain.

Q: What is the ΔG for the transfer of electrons from cytochrome *c* to O_2 ?

 Activity 9.4 **Respiratory Chain** www.Life11e.com/ac9.4

Four large protein complexes (I, II, III, and IV) contain electron carriers and associated enzymes. In eukaryotes they are integral proteins of the inner mitochondrial membrane (see [Figure 5.11](#)), and three are transmembrane proteins.

Cytochrome *c* is a small peripheral protein that lies in the intermembrane space. It is loosely attached to the outer surface of the inner mitochondrial membrane.

Ubiquinone (often referred to as coenzyme Q10; abbreviated Q) is a small, nonpolar, lipid molecule that moves freely within the hydrophobic interior of the phospholipid bilayer of the inner mitochondrial membrane.

As illustrated in [Figure 9.7](#), NADH passes electrons to protein complex I (called NADH-Q reductase), which in turn passes the electrons to Q. This electron transfer is accompanied by a large drop in free energy. Complex II (succinate dehydrogenase) passes electrons to Q from $FADH_2$, which was generated in Step 6 of the citric acid cycle (see [Figure 9.6](#)). These electrons enter the chain later than those from NADH and will ultimately produce less ATP.

Complex III (cytochrome *c* reductase) receives electrons from Q and passes them to cytochrome *c*. Complex IV (cytochrome *c* oxidase) receives electrons from cytochrome *c* and passes them to oxygen. Finally the reduction of oxygen to H_2O occurs:

Notice that four protons (H^+) are also consumed in this reaction. This contributes to the proton concentration gradient across the inner mitochondrial membrane by reducing the proton concentration in the mitochondrial matrix.

ATP is made through chemiosmosis

During electron transport, protons are also actively transported across the membrane: electron transport within each of the three transmembrane complexes (I, III, and IV) results in the transfer of protons from the matrix to the intermembrane space ([Figure 9.8](#)). Since the lipid bilayer does not allow charged H^+ to diffuse across it, transfer of H^+ across it through the electron transport chain sets up a gradient, with the concentration of H^+ in the intermembrane space higher than in the matrix. In addition, because H^+ carries a charge, there is more positive charge in the intermembrane space. These two gradients—of concentration and charge—set up a **proton-motive force** which is a key factor in energy metabolism in cells:

Figure 9.8 The Respiratory Chain and ATP Synthase Produce ATP by a Chemiosmotic Mechanism As electrons pass through the transmembrane protein complexes in the respiratory chain, protons are transferred from the mitochondrial matrix into the intermembrane space. As the protons return to the matrix through ATP synthase, ATP is formed.

Animation 9.1 Electron Transport and ATP Synthesis www.Life11e.com/a9.1

proton-motive force Force generated across a membrane having two components: a chemical potential (difference in proton concentration) plus an electrical potential due to the electrostatic charge on the proton.

The gradient of H^+ across the inner membrane is a source of potential energy.

How can this energy be tapped for use by the cell? The answer is that another protein, ATP synthase, allows the H^+ to diffuse back into the matrix down its concentration gradient. In the process, potential energy is captured and used for the formation of ATP. The coupling of the proton-motive force and ATP synthesis is called the chemiosmotic mechanism—or **chemiosmosis**—and is found in all respiring cells.

chemiosmosis Formation of ATP in mitochondria and chloroplasts, resulting from a pumping of protons across a membrane (against a gradient of electrical charge and of pH), followed by the return of the protons through a protein channel with ATP synthase activity.

To summarize, the energy originally contained in glucose and other fuel molecules is ultimately captured in the cellular energy currency, ATP. For each pair of electrons passed along the chain from NADH to oxygen, about 2.5 molecules of ATP are formed. FADH₂ oxidation produces about 1.5 ATP molecules because it enters the electron transport chain at a later step than NADH (see [Figure 9.8](#)).

ATP synthesis is a reversible reaction, and ATP synthase can also act as an ATPase, hydrolyzing ATP to ADP and P_i:

If the reaction goes to the right, free energy is released. In the mitochondrion, it is used to transfer H⁺ out of the mitochondrial matrix—not the usual mode of operation. If the reaction goes to the left, it uses the free energy from H⁺ diffusion into the matrix to make ATP. What makes it prefer ATP synthesis? There are two answers to this question:

- . ATP leaves the mitochondrial matrix for use elsewhere in the cell as soon as it is made, keeping the ATP concentration in the matrix low, and driving the reaction toward the left.
- . The H⁺ gradient is maintained by electron and proton transport.

Every day a person hydrolyzes about 10²⁵ ATP molecules to ADP. This amounts to 9 kg, a significant fraction of the person's entire body weight! The vast majority of this ADP is “recycled”—converted back to ATP—using free energy from the oxidation of glucose.

Experiments demonstrate chemiosmosis

Because it is so important, chemiosmosis has been subjected to many lab experiments. Let's look at two lines of evidence; first, a direct demonstration in the lab that a H⁺ gradient can drive ATP synthesis, and second, natural disruption of the coupling of electron transport to ATP synthesis.

DIRECT DEMONSTRATION OF CHEMIOSOMOSIS

The key experiment that demonstrated that a proton (H⁺) gradient across a membrane could drive ATP synthesis was first performed using chloroplasts, the organelles in plants that convert the energy in sunlight into chemical energy (photosynthesis; see [Chapter 10](#)) ([Figure 9.9](#)). Soon thereafter, the same mechanism was shown to work in mitochondria.

Figure 9.9 An Experiment Demonstrates the Chemiosmotic Mechanism

Original Paper: Jagendorf, A. T. and E. Uribe. 1966. ATP formation caused by acid-base transition of spinach chloroplasts. *Proceedings of the National Academy of Sciences USA* 55: 170–177.

The chemiosmosis hypothesis was a bold departure from the conventional scientific thinking of the time. It required an intact compartment enclosed by a membrane. Could a proton gradient drive the synthesis of ATP? The first experiments to answer this question used chloroplasts, plant organelles that use the same mechanism as mitochondria to synthesize ATP.

HYPOTHESIS ▶ A H^+ gradient across a membrane that contains ATP synthase is sufficient to drive ATP synthesis.

METHOD

RESULTS

CONCLUSION ▶ A H^+ gradient across an ATP synthase-containing membrane is sufficient for ATP synthesis by organelles.

A **work with the data** exercise that accompanies this figure may be assigned in **LaunchPad**.

Animation 9.2 Two Experiments Demonstrate the Chemiosmotic Mechanism

Activity 9.5 Electron Transport Simulation www.Life11e.com/ac9.5

UNCOUPLING ELECTRON TRANSPORT FROM ATP PRODUCTION

As you have seen, the coupling of electron transport (which generates the proton gradient) with chemiosmosis is vital for the capture of free energy in the form of ATP. Uncoupling protein 1 (UCP1), which is found in the mitochondria of brown fat cells (described in the chapter opening), demonstrates the importance of this coupling. By disrupting the gradient, UCP1 allows the energy released during electron transport to be in the form of heat, rather than chemical energy trapped in ATP.

The relationship between UCP1 in brown fat and body weight has been investigated experimentally in a study of a genetic strain of mice that—unlike normal mice—do not get fat as they age (people tend to put on weight as they age too). As **Investigating Life: Mitochondria, Genetics, and Obesity** reveals, it appears that the leaner mice make more UCP1 and burn off more fat than normal mice do. Might this observation point to ways to control weight gain in people? In a related study of obesity conducted in the 1930s, a chemical, dinitrophenol, was shown to uncouple oxidation and phosphorylation, just as UCP1 (which had not been discovered yet) does. Physicians got the idea that giving obese people the uncoupler would cause them to oxidize (burn off) their fat. It worked, but since dinitrophenol acted on all mitochondria everywhere in the body, and not just in fat cells, severe side effects occurred as ATP production all over the body became critically low—in some cases too low for survival. So the idea of an uncoupler for weight loss was dropped.

HOW ATP SYNTHASE WORKS: A MOLECULAR MOTOR

Now that we have established that the H^+ gradient is needed for ATP synthesis, a question remains: How does the enzyme ATP synthase actually make ATP from ADP and P_i ? This is certainly a fundamental question in biology, as it underlies energy harvesting in most cells. The structure and mechanism of ATP synthase, illustrated in **Figure 9.10A**, are shared by living organisms as diverse as bacteria and humans. ATP synthase is a molecular motor composed of two parts: the F_0 unit, a transmembrane region that is the H^+ channel; and the F_1 unit, which contains the active sites for ATP synthesis. F_1 consists of six subunits (three each of two polypeptide chains), arranged like the segments of an orange around a central shaftlike polypeptide that interacts with the membrane-embedded F_0 . Electron transport sets up an H^+ gradient across the membrane. This gradient has potential energy, and when H^+ diffuses through the channel, the potential energy is converted to kinetic energy, causing the central polypeptide to rotate. The energy is transmitted to the catalytic subunits of F_1 , resulting in ATP synthesis. These molecular motors make ATP at rates up to 100 molecules per second.

experiment

Original Paper: Ma, X., L. Lin, G. Qin, X. Lu, M. Fiorotto, V. Dixit and X. Sun. 2011. Ablations of ghrelin and ghrelin receptor exhibit differential metabolic phenotypes and thermogenic capacity during aging. *PLoS One* 6: e16391.

As people (and mice) get older, they tend to accumulate fat. In the course of investigating a strain of mice genetically unable to make the receptor for a hormone called ghrelin that is involved in controlling appetite, Yuxiang Sun and her team at Baylor College of Medicine compared these mice with normal mice as they aged. They were surprised to find that the genetically changed mice did not put on as much weight as their normal counterparts. The researchers discovered that the genetic mutation in these mice caused uncoupling of oxidative phosphorylation and burning of body fat. Their experiment investigated whether levels of mitochondrial uncoupling protein 1 (UCP1) were different in the genetically changed mice than in normal mice.

HYPOTHESIS ▶ Mice that make more uncoupling protein (UCP1) burn more body fat.

CONCLUSION ▶ Increased UCP1 correlates with less fat and a lower body weight.

METHOD

work with the data

In an effort to determine whether weight gain in normal mice might be due to inactivity or to eating too much (two of the well-known causes of weight gain), as opposed to a biochemical abnormality (such as unusual UCP1 levels), Sun and her team examined young (3–4 months old) and older (10–12 months old) mice of both strains. They measured weight and body composition in terms of fat and lean body tissues. The results are shown in **Figure A**.

QUESTIONS

1. Did the mutant mice and normal mice gain weight as they aged?
2. The researchers wondered whether the weight changes noted in Figure 1 were due to changes in eating patterns or exercising. So they measured how much food the mice ate per day and measured their movements over time in a special chamber. The results are shown in **Figure B**. What can you conclude about the role of food intake and exercise on the weight differences between the two strains of mice?
3. The uncoupling protein UCP1 found in the inner mitochondrial membrane of brown fat cells uncouples mitochondrial electron transport (oxidation) and ATP production (phosphorylation), so that instead of being trapped as chemical energy in the formation of ATP, the energy released by oxidation is released as heat. Sun and her team measured UCP1 levels in brown fat mitochondria of the two strains of mice. The results are shown in **Figure C**. What can you conclude about the role of UCP1 in the weight differences between the two strains of mice?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Figure A

Figure B

Figure C

An ingenious experiment confirmed this rotary motor mechanism. Masasuke Yoshida and his colleagues at the Tokyo Institute of Technology isolated the F_1 portion of the ATP synthase and attached it to a glass slide. Fluorescently labeled microfilaments were attached to the central peptide, and the slide was incubated in a solution containing ATP. In this case there was no proton gradient to drive the molecular motor in the direction of ATP synthesis. Instead, ATP was hydrolyzed to ADP and P_i , and this energy caused the motor to spin. Rotation of the labeled microfilament was visible under a microscope, with the labeled filaments clearly rotating like propellers.

Some microorganisms use non-O₂ electron acceptors

A more general way to describe the last reaction in electron transport is:

Part of the amazing success of bacteria and archaea is that they have evolved biochemical pathways that allow them to exist in environments where O₂ is scarce or absent. As you will see in the next section, for most animals and plants, the anaerobic (no O₂) catabolism of glucose generally yields much less energy than aerobic catabolism. However, many bacteria and archaea exploit their environments to use ***alternative electron acceptors**. This allows them to complete the electron transport chain and produce ATP even in the absence of O₂. [Table 9.2](#) summarizes some of these pathways, which are referred to as **anaerobic respiration**. Note that some of these microbes use ions as electron acceptors while others use small molecules.

table 9.2 Electron Acceptors Used in the Respiratory Chain of Anaerobic Microbes

anaerobic respiration A metabolic pathway in which glucose is catabolized in the absence of oxygen.

9.3 recap

The oxidation of reduced electron carriers in the respiratory chain drives the active transport of protons across the inner mitochondrial membrane, generating a proton-motive force. Diffusion of protons down their electrochemical gradient through ATP synthase is coupled to the synthesis of ATP. Electron transport can form toxic intermediates. Some bacteria and archaea can respire using alternative electron acceptors instead of O₂.

learning outcomes

- Describe how the proton motive force is established by the electron carriers and enzymes of the respiratory chain.
- Analyze experimental results that relate to electron transport and chemiosmosis.
- Predict results from experiments designed to explore aspects of electron transport and chemiosmosis.

1. How are protons transported from the mitochondrial matrix to the intermembrane space

during electron transport?

2. How do the experiments described in [Figures 9.9](#) and [9.10](#) demonstrate the chemiosmotic mechanism?
3. Trace the sequence of changes in redox reactions that occur in mammalian tissue when the oxygen supply is cut off. The first change is that all of the cytochrome c becomes reduced, because electrons can still flow from cytochrome c, but there is no oxygen to accept electrons from cytochrome c oxidase. What happens after this?
4. The drug antimycin A blocks electron transport in mitochondria and chloroplasts. Explain what would happen if the experiment in [Figure 9.9](#) were repeated in the presence of this drug.

Oxidative phosphorylation captures a great deal of energy in ATP. But it does not occur if O₂ is absent. We will turn now to the metabolism of glucose in anaerobic conditions.

***connect the concepts** The diversity of microbial metabolic pathways allows them to adapt to life in many environments. See [Key Concept 25.2](#).

9.4 In the Absence of Oxygen, Some Energy Is Harvested from Glucose

In eukaryotes, in the absence of O_2 (anaerobic conditions), a small amount of ATP can be produced by glycolysis and fermentation. Like glycolysis, fermentation pathways occur in the cytoplasm. There are many different types of fermentation, but they all operate to regenerate NAD^+ so that the NAD^+ -requiring reactions of glycolysis can continue. The two best-understood fermentation pathways are found in a wide variety of organisms, including eukaryotes:

Lactic acid fermentation, the end product of which is lactic acid (lactate)

Alcoholic fermentation, the end product of which is ethyl alcohol (ethanol)

focus your learning

Lactic acid fermentation and alcoholic fermentation are pathways that allow glucose to be oxidized in the absence of oxygen by regenerating oxidized electron carriers.

In [lactic acid fermentation](#), pyruvate serves as the electron acceptor and lactate is the product ([Figure 9.11 A](#)). This process takes place in many microorganisms and complex organisms, including higher plants and vertebrates. A notable example of lactic acid fermentation occurs in vertebrate muscle tissue. Usually, vertebrates get their energy for muscle contraction aerobically, with the circulatory system supplying O_2 to muscles. In small vertebrates, this is almost always adequate: for example, birds can fly long distances without resting. But in larger vertebrates such as humans, the circulatory system is not up to the task of delivering enough O_2 when the need is great, such as during intense activity. At this point, the muscle cells break down glycogen (a stored polysaccharide; see [Figure 3.18](#)) and undergo lactic acid fermentation.

lactic acid fermentation A metabolic pathway in which glucose is catabolized in the absence of oxygen with the production of lactic acid.

(A) Lactic acid fermentation

(B) Alcoholic fermentation

Summary of reactants and products:

Figure 9.11 Fermentation Glycolysis produces pyruvate, ATP, and NADH from glucose. (A) Lactic acid fermentation uses NADH as a reducing agent to reduce pyruvate to lactate, thus regenerating NAD^+ to keep glycolysis operating. (B) In alcoholic fermentation, pyruvate from glycolysis is converted into acetaldehyde, and CO_2 is released. NADH from glycolysis is used to reduce acetaldehyde to ethanol, thus regenerating NAD^+ to keep glycolysis operating.

Lactate buildup becomes a problem after prolonged periods of intense exercise because it is associated with an increase in the H^+ concentration in the cell, lowering the pH. This affects cellular activities, which return to normal upon resting. Lactate dehydrogenase, the enzyme that catalyzes the fermentation reaction, works in both directions. That is, when O_2 is available it can catalyze the oxidation of lactate to form pyruvate, which is then catabolized to CO_2 with concomitant energy release to form ATP. When lactate levels are decreased, muscle activity can resume.

Alcoholic fermentation takes place in certain yeasts (eukaryotic microbes) and some plant cells under anaerobic conditions. This process requires two enzymes, pyruvate decarboxylase and alcohol dehydrogenase, which metabolize pyruvate to ethanol (**Figure 9.11B**). As with lactic acid fermentation, the reactions are essentially reversible. For thousands of years, humans have used anaerobic fermentation by yeast cells to produce alcoholic beverages. The cells use sugars from plant sources (glucose from grapes or maltose from barley) to produce the end product, ethanol, in wine and beer.

alcoholic fermentation See fermentation.

By recycling NAD^+ , fermentation allows glycolysis to continue, thus producing small amounts of ATP through substrate-level phosphorylation. The net yield of two ATPs per glucose molecule is much lower than the energy yield from cellular respiration. For this reason, most organisms existing in anaerobic environments are small microbes that grow relatively slowly.

Cellular respiration yields much more energy than fermentation

The total net energy yield from glycolysis plus fermentation is two molecules of ATP per molecule of glucose oxidized. The maximum yield of ATP that can be harvested from a molecule of glucose through glycolysis followed by cellular respiration is much greater— about 32 molecules of ATP (**Figure 9.12**). (Review **Figures 9.5**, **9.6**, and **9.8**, and p. 180 to see where all the ATP molecules come from.)

Glycolysis and fermentation

Summary of reactants and products:

Glycolysis and cellular respiration

Summary of reactants and products:

Figure 9.12 Cellular Respiration Yields More Energy Than Fermentation Electron

carriers are reduced in pyruvate oxidation and the citric acid cycle, then oxidized by the respiratory chain. These reactions produce ATP via chemiosmosis.

Activity 9.6 Energy Levels www.Life11e.com/ac9.6

Why do the metabolic pathways that operate in aerobic environments produce so much more ATP? Glycolysis and fermentation only partially oxidize glucose. Much more energy remains in the end products of fermentation (lactic acid and ethanol) than in CO_2 , the end product of cellular respiration. In cellular respiration, carriers (mostly NAD^+) are reduced during pyruvate oxidation and the citric acid cycle. Then the reduced carriers are oxidized by the respiratory chain, with the accompanying production of ATP by chemiosmosis (about 2.5 ATP for each NADH and 1.5 ATP for each FADH_2). In an aerobic environment, a cell or organism capable of aerobic metabolism will have the advantage over one that is limited to fermentation, in terms of its ability to harvest chemical energy. Two key events in the evolution of multicellular organisms were the rise in atmospheric O_2 levels (see [Key Concept 25.2](#)) and the development of metabolic pathways to use that O_2 .

The yield of ATP is reduced by the impermeability of mitochondria to NADH

About 32 ATP are produced from the oxidation of one molecule of glucose to CO_2 . However, in many eukaryotes the inner mitochondrial membrane is impermeable to NADH, and a “toll” of one ATP must be paid for each NADH molecule produced in glycolysis that must be “shuttled” into the mitochondrial matrix. So in these organisms, the net yield of ATP is 30.

NADH shuttle systems transfer the electrons captured by glycolysis onto substrates that are capable of movement across the mitochondrial membranes. In muscle and liver tissues (and the brown fat in the opening story), an important shuttle involves glycerol 3-phosphate. In the cytoplasm,

$\text{NADH (from glycolysis)} + \text{dihydroxyacetone phosphate (DHAP)} \rightarrow \text{NAD}^+ + \text{glycerol 3-phosphate}$

Glycerol 3-phosphate is transferred to the outer surface of the inner mitochondrial membrane. At that surface,

The electrons flow from FADH_2 into the electron transport chain via ubiquinone (Q) (see [Figure 9.8](#)). DHAP is able to move back to the cytoplasm, where it is available to repeat the process. Note that the reducing electrons are transferred from NADH to FADH_2 . As you know from [Figure 9.8](#), the energy yield in terms of ATP from FADH_2 is lower than that from NADH. This lowers the overall energy yield.

9.4 recap

In the absence of O_2 , fermentation pathways use NADH formed by glycolysis to reduce pyruvate and regenerate NAD^+ . The energy yield of glycolysis coupled to fermentation is low because glucose is only partially oxidized. When O_2 is present, the electron carriers of cellular respiration allow for the full oxidation of glucose, so the energy yield from glucose is much higher.

learning outcomes

You should be able to:

- Describe the process of fermentation.
-

1. Why is replenishing NAD^+ required to continue glycolysis in the absence of O_2 ?

2. How does fermentation replenish NAD^+ ?

Now that you've seen how cells harvest energy, let's see how that energy moves through other metabolic pathways in the cell.

9.5 Metabolic Pathways Are Interrelated and Regulated

Glycolysis and the pathways of cellular respiration do not operate in isolation. Rather, there is an interchange of molecules into and out of these pathways, to and from the metabolic pathways for the synthesis and breakdown of amino acids, nucleotides, fatty acids, and other building blocks of life (see [Figure 8.14](#)). Carbon skeletons (i.e., the carbon backbones of organic molecules) can enter the catabolic pathways and be broken down to release their energy, or they can enter anabolic pathways to be used in the formation of the macromolecules that are the major constituents of the cell. These relationships are summarized in [Figure 9.13](#). In this section we will explore how pathways are interrelated by the sharing of intermediate molecules, and we will see how pathways are regulated by the inhibitors of key enzymes.

Figure 9.13 Relationships among the Major Metabolic Pathways of the Cell Note the central positions of glycolysis and the citric acid cycle in this network of metabolic pathways. Also note that many of the pathways can operate essentially in reverse.

Q: Can DNA be an energy source? Explain. Why do you think it is not usually employed in this way?

focus your learning

The synthesis and breakdown of macromolecules in a cell are linked through common metabolic pathways.

Metabolic pathways are regulated to ensure efficiency and proper functioning of the cell.

Catabolism and anabolism are linked

A hamburger or veggie burger on a bun contains three major sources of carbon skeletons: carbohydrates, mostly in the form of starch (a polysaccharide); lipids, mostly as triglycerides (three fatty acids attached to glycerol); and proteins (polymers of amino acids). Look at [Figure 9.13](#) to see how each of these three types of macromolecules can be hydrolyzed and used in catabolism or anabolism.

CATABOLIC INTERCONVERSIONS

Polysaccharides, lipids, and proteins can all be broken down to provide energy:

Polysaccharides are hydrolyzed to glucose. Glucose then passes through glycolysis and cellular respiration, where its energy is captured in ATP.

Lipids are broken down into their constituents, glycerol and fatty acids. Glycerol is converted into dihydroxyacetone phosphate (DHAP), an intermediate in glycolysis. Fatty acids are highly reduced molecules that are converted to acetyl CoA inside the mitochondrion by a series of oxidation enzymes, in a process known as β -oxidation. For example, the β -oxidation of a 16-carbon (C_{16}) fatty acid occurs in several steps:

The acetyl CoA can then enter the citric acid cycle and be catabolized to CO_2 .

Proteins are hydrolyzed to their amino acid building blocks. The 20 different amino acids feed into glycolysis or the citric acid cycle at different points determined by their structures. For example, the amino acid glutamate is converted into α -ketoglutarate, an intermediate in the citric acid cycle (the five-carbon molecule in [Figure 9.6](#)).

ANABOLIC INTERCONVERSIONS

Many catabolic pathways can operate essentially in reverse, with some modifications. Glycolytic and citric acid cycle intermediates, instead of being oxidized to form CO_2 , can be reduced and used to form glucose in a process called **gluconeogenesis** (which means “new formation of glucose”). Likewise, acetyl CoA can be used to form fatty acids. The most common fatty acids have even numbers of carbons: 14, 16, or 18. These are formed by the addition of two-carbon acetyl CoA “units” one at a time until the appropriate chain length is reached. Acetyl CoA is also a building block for various pigments, plant growth substances, rubber, steroid hormones, and other molecules.

gluconeogenesis The biochemical synthesis of glucose from other substances, such as amino acids, lactate, and glycerol.

Some intermediates in the citric acid cycle are reactants in pathways that synthesize important components of nucleic acids. For example, α -ketoglutarate is a starting point for purines, and oxaloacetate for pyrimidines. In addition, α -ketoglutarate is a starting point for the synthesis of chlorophyll (used in photosynthesis; see [Chapter 10](#)) and the amino acid glutamate (used in protein synthesis).

Catabolism and anabolism are integrated

A carbon atom from a protein in your burger can end up in DNA, fat, or CO_2 , among other fates. How does the organism “decide” which metabolic pathways to follow, in which cells? With all of the possible interconversions, you might expect that cellular concentrations of various biochemical molecules would vary widely. Remarkably, the levels of these substances in what is called the metabolic pool—the sum total of all the biochemical molecules in a cell—are quite constant. Organisms regulate the ***enzymes** in various cells in order to maintain a steady state between catabolism and anabolism. For example, let’s look at how glucose levels are maintained in the body during exercise ([Figure 9.14](#)).

Figure 9.14 Interactions of Catabolism and Anabolism during Exercise When we walk or run, muscle cells in our legs and heart catabolize glucose for energy, while liver cells produce glucose by anabolism to feed the needs of the muscles.

When you're walking or jogging, the muscles that most need energy are the leg muscles that power movement and the heart muscles that circulate blood. The energy comes from the catabolism of glucose by glycolysis, the citric acid cycle, and oxidative phosphorylation. These muscles therefore need a lot of glucose. Some glycogen is stored in the leg muscles and is hydrolyzed to glucose monomers. In addition, glycogen is hydrolyzed in the liver, which releases the glucose into the blood. As this glucose is used up by the working muscles, more glucose is made in the liver by anabolism from amino acids and pyruvate. Some of this pyruvate comes from lactate formed by fermentation in the leg muscles and that has been transported back to the liver in the blood.

The exquisite integration of catabolism and anabolism cannot be accomplished without control points in the biochemical pathways. For example, something must "tell" the liver to make glucose rather than catabolizing it or storing it. How are the systems integrated?

Metabolic pathways are regulated systems

The regulation of interconnecting biochemical pathways is a problem of systems biology, which seeks to understand how biochemical pathways interact (see [Key Concept 8.5](#)). It is a bit like trying to predict traffic patterns in a city: if an accident blocks traffic on a major road, drivers take alternate routes, where the traffic volume consequently changes.

Several mechanisms can be used to regulate the rate of each step in a biochemical pathway:

Changing the amount of active enzyme: The cell can increase the expression of a gene encoding an enzyme.

Changing enzyme activity by covalent modifications: Adding phosphate groups by protein kinase can alter the activity of an enzyme.

Feedback inhibition: Allosteric changes in an enzyme due to binding of a product in a pathway can cause the entire pathway to shut down.

Substrate availability: If the substrate of a particular enzyme is used up by another pathway, the first enzyme can no longer function and the pathway shuts down.

Consider what happens to the starch in your burger bun. In the digestive system, starch is hydrolyzed to glucose, which enters the blood for distribution to the rest of the body. But before

the glucose is distributed, a regulatory check must be made: If there is already enough glucose in the blood to supply the body's needs, the excess glucose is converted into glycogen and stored in the liver and muscles. If not enough glucose is supplied by food, glycogen is broken down, or other molecules are used to make glucose by gluconeogenesis. The end result is that the level of glucose in the blood is remarkably constant. How does the body accomplish this?

Glycolysis and the citric acid cycle are subject to allosteric regulation (see [Key Concept 8.5](#)) of key enzymes involved. In a metabolic pathway, a high concentration of the final product can inhibit the action of an enzyme that catalyzes an earlier reaction (see [Figure 8.18](#)). Furthermore, an excess of the product of one pathway can activate an enzyme in another pathway, speeding up its reactions and diverting raw materials away from synthesis of the first product ([Figure 9.15](#)). These negative and positive feedback mechanisms are used at many points in the energy-harvesting pathways and are summarized in [Figure 9.16](#).

Figure 9.15 Regulation by Negative and Positive Feedback Allosteric feedback regulation plays an important role in metabolic pathways. The accumulation of some products can shut down their synthesis, or can stimulate other pathways that require the same raw materials.

Activity 9.7 Regulation of Energy Pathways www.Life11e.com/ac9.7

Figure 9.16 Allosteric Regulation of Glycolysis and the Citric Acid Cycle

Allosteric regulation controls glycolysis and the citric acid cycle at crucial early steps, increasing their efficiency and preventing the excessive buildup of intermediates.

The main control point in glycolysis is the glycolytic enzyme phosphofructokinase, which catalyzes Step 3 in [Figure 9.5](#). This enzyme is allosterically inhibited by ATP or citrate, and activated by ADP or AMP. Under anaerobic conditions, fermentation yields a relatively small

amount of ATP, and phosphofructokinase operates at a high rate. However, when conditions are aerobic, respiration makes 16 times more ATP than fermentation does, and the abundant ATP allosterically inhibits phosphofructokinase. So glycolysis slows down.

The main control point in the citric acid cycle is the enzyme isocitrate dehydrogenase (which catalyzes Step 3 in [Figure 9.6](#)). This enzyme is activated by increases in substrate concentrations (ADP, NAD^+ , and isocitrate) and is inhibited by products of the citric acid cycle: ATP and NADH. If too much ATP or NADH accumulates, the reaction is slowed, and the citric acid cycle shuts down.

Another control point involves acetyl CoA. If the level of ATP is high and the citric acid cycle shuts down, the accumulation of citrate activates fatty acid synthase, diverting acetyl CoA to the synthesis of fatty acids for storage (contributing to a person's accumulation of fat). These fatty acids may be metabolized later to produce more acetyl CoA.

9.5 recap

Glucose can be made from intermediates in glycolysis and the citric acid cycle by gluconeogenesis. The metabolic pathways for the production and breakdown of lipids and amino acids are linked to those of glucose metabolism. Reaction products regulate key enzymes in the various pathways.

learning outcomes

You should be able to:

- Describe catabolic and anabolic pathways that link carbohydrate, lipid, and protein metabolism.
 - Trace the path of an atom as it moves through various metabolic pathways within a cell.
 - Explain how allosteric changes in an enzyme can be used to regulate flow through a metabolic pathway.
-
1. Give examples of the pathways relating to glycolysis and the citric acid cycle for catabolism of a lipid and the anabolism of a protein.
 2. How does phosphofructokinase serve as a control point for glycolysis?
 3. You eat a burger that contains polysaccharides, proteins, and lipids. How could carbon atoms in the proteins' amino acids and the glucose in the polysaccharides end up as fats?

investigatinglife

How are mitochondria related to obesity?

Recall from the opening of this chapter that brown fat is adipose tissue with a high concentration of mitochondria, which have iron-containing pigments. The uncoupling protein UCP1, found in the inner membranes of mitochondria in brown fat cells, uncouples mitochondrial electron transport (oxidation) and ATP production (phosphorylation), so that instead of being trapped as chemical energy in the formation of ATP, the energy released by oxidation is released as heat.

Hibernating animals take advantage of the heat emitted by the catabolism of energy-rich molecules in brown fat, especially when aroused. In hibernating animals, brown fat and UCP1 increase during the

winter. It turns out that adult humans also experience a seasonal variation in brown fat, having more of it in the cooler months. Other factors such as diet and exercise being equal, increased fat catabolism occurs in the presence of UCP1 (as demonstrated by the experiment in Investigating Life: Mitochondria, Genetics, and Obesity).

Genetic studies confirm the role of UCP1 in fat breakdown as well. For example, some people have a genetically determined variant of UCP1 that has lower uncoupling activity than normal UCP1. As people with the variant get older, they accumulate more body fat than their peers with normal UCP1 do.

Future directions

The recent finding that not just babies but also adults have mitochondria-laden brown fat has sparked interest in the possible activation of these cells to treat obesity. In addition to occurring in well-known locations such as the neck and shoulders, brown fat cells have been found mixed in with non-brown fat all over the body, and can be seen by PET (positron emission tomography) scans. At the U.S. National Institutes of Health, a research team led by Aaron Cypess has found unexpectedly that a drug used to treat people with an overactive bladder also activates fat breakdown in brown fat cells. The drug, mirabegron, targets a receptor on bladder cells that is also expressed on brown fat cells. When people without bladder disease were given this drug, brown fat cells were activated. There was increased glucose uptake and heat production due to mitochondrial uncoupling, and also an eightfold increase in fatty acid breakdown by the mitochondria. This could be a promising treatment for disorders that lead to obesity.

► 9.1 Cells Harvest Chemical Energy from Glucose Oxidation

- As a material is **oxidized**, the electrons it loses are transferred to another material, which is thereby **reduced**. Such [oxidation-reduction](#), or **redox**, **reactions** transfer large amounts of energy. **Review** [Figure 9.2](#)

oxidation–reduction (redox) reaction A reaction in which one substance transfers one or more electrons to another substance. (See oxidation, reduction.)

- The coenzyme NAD^+ is a key electron carrier in biological redox reactions. It exists in two forms, one oxidized (NAD^+) and the other reduced (NADH). **Review Focus: Key** [Figure 9.3](#)
- [Glycolysis](#) does not use O_2 . Under [aerobic](#) conditions, [cellular respiration](#) continues the process of breaking down glucose. Under anaerobic conditions, fermentation occurs. **Review** [Figures 9.1, 9.4, Activities 9.1, 9.2](#)

glycolysis (gly kol' li sis) [Gk. *gleukos*: sugar + *lysis*: break apart] The enzymatic breakdown of glucose to pyruvic acid.

aerobic (air oh' bic) [Gk. *aer*: air + *bios*: life] In the presence of oxygen; requiring or using oxygen (as in **aerobic metabolism**). (Contrast with anaerobic.)

cellular respiration The catabolic pathways by which electrons are removed from various molecules and passed through intermediate electron carriers to O_2 , generating H_2O and releasing energy.

- The pathways of cellular respiration after glycolysis are pyruvate oxidation, the citric acid cycle, and electron transport/ATP synthesis.

► 9.2 In the Presence of Oxygen, Glucose Is Fully Oxidized

- Glycolysis consists of ten enzyme-catalyzed reactions that occur in the cell cytoplasm. Two [pyruvate](#) molecules are produced for each partially oxidized molecule of glucose, providing the starting material for both cellular respiration and fermentation. **Review** [Figure 9.5](#)

pyruvate The ionized form of pyruvic acid, a three-carbon acid; the end product of glycolysis and the raw material for the citric acid cycle.

- Pyruvate oxidation follows glycolysis and links glycolysis to the citric acid cycle. This pathway converts pyruvate into **acetyl CoA**.
- Acetyl CoA is the starting point of the **citric acid cycle**. It reacts with oxaloacetate to produce citrate. A series of eight enzyme-catalyzed reactions oxidize citrate and regenerate oxaloacetate, continuing the cycle. **Review** [Figure 9.6, Activity 9.3](#)

▶ 9.3 Oxidative Phosphorylation Forms ATP

- Oxidation of electron carriers in the presence of O_2 releases energy that can be used to form ATP in a process called [oxidative phosphorylation](#).

oxidative phosphorylation ATP formation in the mitochondrion, associated with flow of electrons through the respiratory chain.

- The NADH and $FADH_2$ produced in glycolysis, pyruvate oxidation, and the citric acid cycle are oxidized by the [respiratory chain](#), regenerating NAD^+ and FAD. Oxygen (O_2) is the final acceptor of electrons and protons, forming water (H_2O). **Review** [Figure 9.7](#), [Activity 9.4](#)

respiratory chain The terminal reactions of cellular respiration, in which electrons are passed from NAD or FAD, through a series of intermediate carriers, to molecular oxygen, with the concomitant production of ATP.

- The respiratory chain not only transports electrons, but also transfers protons across the inner mitochondrial membrane, creating the [proton-motive force](#).

proton-motive force Force generated across a membrane having two components: a chemical potential (difference in proton concentration) plus an electrical potential due to the electrostatic charge on the proton.

- Protons driven by the proton-motive force can return to the mitochondrial matrix via [ATP synthase](#), a molecular motor that couples this movement of protons to the synthesis of ATP. This process is called [chemiosmosis](#). **Review** [Figure 9.8](#), [Activity 9.5](#)

ATP synthase An integral membrane protein that couples the transport of protons with the formation of ATP.

chemiosmosis Formation of ATP in mitochondria and chloroplasts, resulting from a pumping of protons across a membrane (against a gradient of electrical charge and of pH), followed by the return of the protons through a protein channel with ATP synthase activity.

- There is considerable experimental evidence for chemiosmosis. **Review** [Figures 9.9](#), [9.10](#), [Animations 9.1](#), [9.2](#)

▶ 9.4 In the Absence of Oxygen, Some Energy Is Harvested from Glucose

- In the absence of O_2 in most organisms, glycolysis is followed by fermentation. Together, these pathways partially oxidize pyruvate and generate end products such as lactic acid or ethanol. In the process, NAD^+ is regenerated from NADH so that glycolysis can continue, thus generating a small amount of ATP. **Review** [Figure 9.11](#)
- For each molecule of glucose used, glycolysis plus fermentation yields two molecules of ATP. In contrast, glycolysis operating with pyruvate oxidation, the citric acid cycle, and oxidative phosphorylation yields up to 32 molecules of ATP per molecule of glucose. **Review** [Figure 9.12](#), [Activity 9.6](#)

▶ 9.5 Metabolic Pathways Are Interrelated and Regulated

- The catabolic pathways for the breakdown of carbohydrates, fats, and proteins feed into the energy-harvesting metabolic pathways. **Review** [Figure 9.13](#)
- Anabolic pathways use intermediate components of the energy-harvesting pathways to synthesize fats, amino acids, and other essential building blocks.
- The formation of glucose from intermediates of glycolysis and the citric acid cycle is called [gluconeogenesis](#).

gluconeogenesis The biochemical synthesis of glucose from other substances, such as amino acids, lactate, and glycerol.

- The rates of glycolysis and the citric acid cycle are controlled by allosteric regulation and by the diversion of excess acetyl CoA into fatty acid synthesis. Key regulated enzymes include phospho-fructokinase, citrate synthase, isocitrate dehydrogenase, and fatty acid synthase. **!!See** [Figure 9.16](#), [Activity 9.7](#)

Original Papers: Cahill, Jr., G. F. 2006. Fuel metabolism in starvation. *Annual Review of Nutrition* 26: 1–2.

Exton, J. H. and C. R. Park. 1967. Control of gluconeogenesis in liver: I. General features of gluconeogenesis in the perfused livers of rats. *Journal of Biological Chemistry* 242: 2622–2636.

People desperate to lose weight quickly sometimes resort to crash diets, which involve severely limiting foods rich in energy. But how effective is this strategy? What happens to the body when it is starved of food? Scientists have studied starvation in mammals to find out how their bodies compensate for a lack of food. Their findings can be used to better understand the effects of severe diets on the human body.

Studies have shown that mammalian bodies need a constant supply of glucose to maintain homeostasis. Food provides a regular supply of glucose, and when there is an excess, the body stores it as glycogen. [Figure A](#) shows how cells in the human body shift in their rate of glucose oxidation and the source of glucose oxidized after food intake has stopped.

These data indicate that once glycogen reserves are used up, the body uses other molecules as sources of glucose. What are these molecules? To find out, researchers studied the biochemistry of the liver, since it is the major organ where glucose is made (gluconeogenesis). They surgically removed livers from healthy rats and kept the livers in an active physiological state using perfusion. Perfusion is a technique that pumps fluids through the blood vessels of an organ to mimic the normal blood flow taking place inside a living animal. Using perfused rat livers, the researchers tested the production of glucose inside liver cells when various metabolic compounds were pumped through the isolated livers. They did this by measuring glucose

concentration (mM) in the perfusion fluid leaving the livers. The results of their studies are shown in [Figure B](#) and the table. (The data in [Figure B](#) were gathered from the livers of fasted rats.)

Figure B

Experiment number	Condition	Additions	Rate of glucose production through gluconeogenesis (μmoles/g liver/hr)
1	Fasted rats	Protein	55.0
2	Fasted rats	Fatty acid + protein	58.9
3	Fed rats	No addition	105.4
4	Fed rats	Fatty acid	99.0

Questions

1. According to data in [Figure A](#), what does the human body do to supply glucose to its organs once food intake stops?
2. Most people want to lose fat when they diet. Ideally, these people would like their fat to be used as fuel when they restrict their food intake. Recall that triglycerides are one form of fat stored in the body, and that a triglyceride is composed of a glycerol molecule bonded to three fatty acid molecules. Also recall that proteins are composed of amino acids. Assuming that all mammals respond as rats do, what do the data from the rat perfusion studies suggest about the identities of the molecules that mammalian bodies use to make glucose under starvation conditions?
3. Considering your answer to Question 2, and assuming that all mammals respond as rats do, what is likely to happen to the muscles of a person who goes on an extreme calorie-restriction diet as a way to lose weight? Is this advisable? Do you think people realize these consequences when they attempt losing

weight via crash diets?

1. Alanine is an amino acid that has been shown to be an important intermediate in the gluconeogenesis pathway. Find and compare the structures of alanine and pyruvate. Show how an atom in an alanine molecule could be radiolabeled so that it could be traced through the formation of pyruvate as part of the gluconeogenesis pathway.

Saving FACE

In July 2014, a satellite was launched into space to measure photosynthesis over all of Earth. The Orbiting Carbon Observatory has instruments aboard that map not only the concentration of carbon dioxide, but also the presence of the green plant pigment chlorophyll. Why these measurements, and why now?

As you may know, green plants use the pigment chlorophyll in photosynthesis, which has the general equation

The orbiting satellite is measuring chlorophyll, a reflection of the presence of green plants, and CO_2 over time because the global atmosphere and biological communities are changing. Over the past 200 years, the concentration of atmospheric CO_2 has increased—from 280 parts per million (ppm) in the year 1800 to 400 ppm in 2016—and the increase will probably continue for some time. Carbon dioxide is a “greenhouse gas” that traps heat in the atmosphere, and the rising CO_2 level is resulting in global climate change. Plant biologists are being asked two questions about the rise in CO_2 : will it lead to an increased rate of photosynthesis, and if so, will it lead to increased plant growth?

To answer these questions, scientists developed a way to expose plants to high levels of CO_2 in the field. Free-air concentration enrichment (FACE) uses rings of pipes to release CO_2 into the air surrounding plants in fields or forests. Wind speed and direction are monitored by a computer, which constantly controls which pipes release CO_2 . These experiments confirm that photosynthetic rates increase as the concentration of CO_2 rises, and indicate that as atmospheric CO_2 rises globally, there will be an increase in photosynthesis.

Will this increase in photosynthesis result in an increase in plant growth? Keep in mind that plants, like all organisms, use carbohydrates as an energy source. They perform cellular respiration with the general equation

The challenge facing plant biologists is to determine the balance between photosynthesis and respiration and how this affects the rate of plant growth. The FACE experiments indicate that plant growth and crop yields increase under higher CO_2 concentrations, suggesting that the overall increase in photosynthesis is greater than the increase in respiration.

QA What is the chemistry of photosynthesis, and how will it be affected by rising atmospheric CO_2 ?

10.1 Photosynthesis Uses Light to Make Carbohydrates

Recall that catabolism—the breakdown of complex molecules into simpler units—is the reverse of anabolism—the construction of complex molecules from simpler units. [Chapter 9](#) described several energy-releasing catabolic pathways. The energy stored in chemical bonds in almost all organisms (with the exception of those living near deep-sea vents) ultimately comes from the sun. **Photosynthesis** (literally, “synthesis from light”) is an anabolic process by which the energy of sunlight is captured and used to convert carbon dioxide (CO₂) into more complex carbon-containing compounds.

photosynthesis (foe tow sin' the sis) [Gk. creating from light] Metabolic processes carried out by green plants and some microorganisms by which visible light is trapped and the energy used to synthesize compounds such as ATP and glucose.

focus your learning

Water molecules supply the protons and electrons needed to reduce carbon dioxide to carbohydrate in oxygenic photosynthesis.

Photosynthesis occurs via two sequential reactions: light reactions followed by light-independent reactions.

Photosynthesis involves light and gas exchange

Plants, algae, and cyanobacteria live in aerobic environments and carry out oxygenic photosynthesis: the conversion of CO₂ and water (H₂O) into carbohydrates (which we will represent as a six-carbon sugar, C₆H₁₂O₆) and oxygen gas (O₂) ([Figure 10.1](#)).

Figure 10.1 The Ingredients for Photosynthesis A typical terrestrial plant uses light from the sun, water from the soil, and carbon dioxide from the atmosphere to form organic compounds by photosynthesis.

Some kinds of bacteria live in anaerobic environments and carry out a type of photosynthesis in which energy from the sun is used to convert CO₂ to more complex molecules without the production of O₂. We will describe this process in more detail below, but first let's look at oxygenic photosynthesis.

[Equation 10.1](#) describes an endergonic reaction. From experiments such as the ones described in the chapter-opening story using FACE, the role of CO₂ is well established. But while the equation is essentially correct, it is too general for a real understanding of the processes involved. Several questions arise: What are the precise chemical reactions of photosynthesis? What role does light play in these reactions? How do carbons become linked to form carbohydrates? What carbohydrates are formed? And does the oxygen gas come from CO₂ or H₂O?

Experiments with isotopes show that O₂ comes from H₂O in oxygenic photosynthesis

In 1941 Samuel Ruben and Martin Kamen at the University of California, Berkeley performed

experiments using the isotopes ^{18}O and ^{16}O to identify the source of the O_2 produced during photosynthesis (**Investigating Life: What Is the Chemistry of Photosynthesis, and How Will Increasing CO_2 in the Atmosphere Affect It?**). Their results showed that all the oxygen gas produced during photosynthesis comes from water, as is reflected in the revised balanced equation:

Water appears on both sides of the equation because it is both used as a reactant (the 12 molecules on the left) and released as a product (the 6 new molecules on the right). This revised equation accounts for all the water molecules needed for all the oxygen gas produced.

The realization that water was the source of photosynthetic O_2 led to an understanding of photosynthesis in terms of oxidation and reduction. As you learned in [Chapter 9](#), oxidation-reduction (redox) reactions are coupled: when one molecule becomes oxidized in a reaction, another gets reduced. In this case, oxygen atoms in the reduced state in H_2O get oxidized to O_2 :

while carbon atoms in the oxidized state in CO_2 get reduced to carbohydrate, with the simultaneous production of water:

Adding [Equations 10.3](#) and [10.4](#) (chemistry students will recognize them as half-cell reactions) gives the overall [Equation 10.2](#) shown above.

As you have just seen, water is the donor of protons and electrons in oxygenic photosynthesis. Earlier, we mentioned a type of photosynthesis that does not produce O_2 . In these cases, other molecules are used as electron donors in the reduction of CO_2 to carbohydrates. For example, purple sulfur bacteria use hydrogen sulfide (H_2S) as the electron donor:

 What is the Chemistry of Photosynthesis, and How Will Increasing CO_2 in the Atmosphere Affect It?

experiment

Original Paper: Ruben, S., M. Randall, M. D. Kamen and J. L. Hyde. 1941. Heavy oxygen (^{18}O) as a tracer in the study of photosynthesis. *Journal of the American Chemical Society* 63(3): 877–879.

Understanding the chemical reactions of photosynthesis is key to understanding the effects of increasing atmospheric CO_2 . In particular, the source of O_2 was not known. Two possibilities were the reactants, CO_2 and H_2O . In two separate experiments, Samuel Ruben and Martin Kamen labeled the oxygen in these molecules with the isotope ^{18}O , then tested the O_2 produced by a green plant to find out which molecules contributed the oxygen.

HYPOTHESIS▶ The oxygen released by photosynthesis comes from water rather than CO_2 .

METHOD

Give plants isotope-labeled water and unlabeled CO_2 .

Experiment 1

Experiment 2

Give plants isotope-labeled CO_2 and unlabeled water.

RESULTS

The oxygen released is labeled.

The oxygen released is unlabeled.

CONCLUSION▶ Water is the source of the oxygen atoms in the O_2 produced by photosynthesis.

work with the data

In the 1930s, Cornelius van Niel, then a graduate student at Stanford University, was the first to propose that the oxygen released during photosynthesis is not actually derived from carbon dioxide, but rather from the water molecules consumed in the reaction. This hypothesis was formed on the basis of the discovery that the anaerobic purple sulfur bacteria do not release oxygen during photosynthesis. Instead, these organisms convert hydrogen sulfide (H_2S) into elemental sulfur in their photosynthetic pathway (see Equation 10.5). This hypothesis was later confirmed by the experiment outlined above, which employed the “heavy” isotope of oxygen, ^{18}O , to trace the flow of oxygen in plants.

As part of the expanding research on radioisotopes during World War II, the U.S. government set up a radiation laboratory at the University of California, Berkeley. Out of this lab came key experi-

ments that described the light-dependent and light-independent pathways of photosynthesis. In this set of experiments, *Chlorella* algal cells were exposed to water and CO_2 , the latter coming from potassium carbonate (K_2CO_3) and potassium bicarbonate (KHCO_3), which dissolve in water to form CO_2 . In Experiment 1, water had a higher isotopic ratio of $^{18}\text{O}/^{16}\text{O}$ than CO_2 and in Experiment 2, CO_2 had a higher isotopic ratio than water. A mass spectrometer was used to measure the isotopic contents of the reactants and the O_2 produced, and the data were presented as the isotopic ratio ($^{18}\text{O}/^{16}\text{O}$). These data are shown in the table.

QUESTIONS

1. In Experiment 1, was the isotopic ratio of O_2 similar to that of H_2O or to that of CO_2 ? What about in Experiment 2?
2. What can you conclude from these data?

	Time before start of O_2 collection (min)	Time at end of O_2 collection (min)	$^{18}\text{O}/^{16}\text{O}$ (proportion ^{18}O in compound)		
			H_2O	$\text{HCO}_3^- + \text{CO}_3^{2-}$ (CO_2 sources)	O_2
Experiment 1: 0.09 M KHCO_3 + 0.09 M K_2CO_3 (^{18}O in H_2O)	0		0.85	0.20	
	45	110	0.85	0.41	0.84
	110	223	0.85	0.55	0.85
	225	350	0.85	0.61	0.86
Experiment 2: 0.14 M KHCO_3 + 0.06 M K_2CO_3 (^{18}O in CO_2)	0		0.20		
	40	110	0.20	0.50	0.20
	110	185	0.20	0.40	0.20

Animation10.1 The Source of the Oxygen
Produced by Photosynthesis
www.Life11e.com/a10.1

A similar **work with the data** exercise may be assigned in **LaunchPad**

Green sulfur bacteria use sulfide ions, hydrogen, or ferrous iron as electron donors, whereas another group of bacteria use compounds derived from arsenic. The remainder of this chapter will focus on oxygenic photosynthesis, which produces the vast majority of the organic carbon used by life on Earth today and replenishes the O_2 in our atmosphere.

Photosynthesis involves two pathways

[Equation 10.2](#) above summarizes the overall process of photosynthesis, but not the steps by which it happens. Water serves as the electron donor, but there is an intermediary carrier of the H^+ and electrons between the oxidation and reduction reactions. The carrier is the coenzyme nicotinamide adenine dinucleotide phosphate (NADP⁺).

Like glycolysis and the other metabolic pathways that harvest energy in cells, photosynthesis has many steps. These reactions are commonly divided into two main pathways:

- The **light reactions** convert light energy into chemical energy in the form of ATP and the reduced electron carrier NADPH. This molecule is similar to the coenzyme NADH (see [Key Concept 9.1](#)) but with an additional phosphate group attached to the sugar of its adenosine. In general, NADPH acts as a reducing agent in photosynthesis and other anabolic reactions.
- The **light-independent reactions** (carbon-fixation reactions) do not use light directly, but instead use ATP, NADPH (made by the light reactions), and CO_2 to produce carbohydrate.

light reactions The initial phase of photosynthesis, in which light energy is converted into chemical energy.

light-independent reactions Reactions that follow the light reaction and use the energy captured in the light reactions to drive the reduction of CO_2 to form carbohydrates.

The light-independent reactions are sometimes called the dark reactions because they do not directly require light energy. They are also called the carbon-fixation reactions because by these reactions inorganic carbon is assimilated, or “fixed,” into organic compounds. However, in most plants both the light reactions and the light-independent reactions *stop in the dark* because ATP synthesis and NADP⁺ reduction require light. So to be accurate, we use the term light-independent reactions. The reactions of both pathways proceed within the chloroplast, but they are compartmentalized, occurring in different parts of that organelle (**Focus: Key Figure 10.2**).

focus: key figure

Figure 10.2 An Overview of Photosynthesis Photosynthesis consists of two pathways: the light reactions and the light-independent reactions. These reactions take place in the thylakoids and the stroma of chloroplasts, respectively. See [Figure 5.12](#) for more on the structure of chloroplasts.

Q: In the cell, where does the reduction of CO_2 occur and what is the reducing agent?

As we describe these two series of reactions in more detail, you will see that they conform to the principles of biochemistry that we discussed in [Chapters 8](#) and [9](#): energy transformations, oxidation-reduction, and the stepwise nature of biochemical pathways.

10.1 recap

The light reactions of photosynthesis convert light energy into chemical energy. The light-independent reactions use that chemical energy to reduce CO_2 to carbohydrates. While most photosynthetic organisms use water as the electron donor for reduction of CO_2 , some use other molecules, such as hydrogen sulfide (H_2S).

learning outcomes

You should be able to:

- Use experimental evidence to explain the source of the O_2 produced in oxygenic photosynthesis.
- Describe the relationship between the light reactions and the light-independent reactions of photosynthesis.

-
- [1.](#) What is the relationship between the light reactions and the light-independent reactions of photosynthesis?
 - [2.](#) What is the experimental evidence that water is the source of the O_2 produced during photosynthesis?

We will describe the light reactions and the light-independent reactions separately. We'll begin the next section by discussing the physical nature of light and the specific photosynthetic molecules that capture its energy.

10.2 Photosynthesis Converts Light Energy into Chemical Energy

Light is a form of energy, and it can be converted to other forms of energy such as heat or chemical energy. Our focus here will be on light as the source of energy to drive the formation of ATP (from ADP and P_i) and NADPH (from $NADP^+$ and H^+).

focus your learning

Plants have pigment molecules that receive light energy and convert it to chemical energy in the form of excited electrons.

Electron transport systems and two coordinated photosystems harvest the chemical energy of excited electrons to produce NADPH and ATP.

Light energy is absorbed by pigments in photosynthesis

It is helpful here to discuss light in terms of its photochemistry and photobiology.

PHOTOCHEMISTRY

Light is a form of [electromagnetic radiation](#). Electromagnetic radiation is said to have a dual nature. Although it is propagated in waves, it also has particle-like behaviors. Particles of light can be described as packets of energy called [photons](#), which have no mass. The amount of energy in electromagnetic radiation is inversely proportional to its [wavelength](#)—the shorter the wavelength, the greater the energy. The visible portion of the electromagnetic spectrum ([Figure 10.3](#)) encompasses a wide range of wavelengths and energy levels. In plants and other photosynthetic organisms, receptive molecules absorb photons and thereby harvest their energy for biological processes. These receptive molecules absorb only specific wavelengths of light—photons with specific amounts of energy.

electromagnetic radiation A self-propagating wave that travels through space and has both electrical and magnetic properties.

photon (foe' ton) [Gk. *photos*: light] A quantum of visible radiation; a “packet” of light energy.

wavelength The distance between successive peaks of a wave train, such as electromagnetic radiation.

Figure 10.3 The Electromagnetic Spectrum The portion of the electromagnetic spectrum that is visible to humans as light is shown in detail at the top.

When a photon meets a molecule, one of three things can happen:

- . The photon may bounce off the molecule—it may be scattered or reflected.
- . The photon may pass through the molecule—it may be transmitted.
- . The photon may be absorbed by the molecule, adding energy to the molecule.

Neither of the first two outcomes causes any change in the molecule. However, in the case of absorption, the photon disappears and its energy is absorbed by the molecule. The photon's energy cannot disappear, because according to the first law of thermodynamics, energy is neither created nor destroyed. When the molecule acquires the energy of the photon, it is raised from a ground state (with lower energy) to an excited state (with higher energy):

The difference in free energy between the molecule's excited state and its ground state is approximately equal to the free energy of the absorbed photon (a small amount of energy is lost to entropy, according to the second law of thermodynamics). The increase in energy boosts one of the electrons in the molecule into a *shell farther from its nucleus; this electron is now held less firmly, making the molecule unstable and more chemically reactive.

PHOTOBIOLOGY

The specific wavelengths absorbed by a particular molecule are characteristic of that type of molecule. Molecules that absorb wavelengths in the visible spectrum are called **pigments**.

pigment A substance that absorbs visible light.

When a beam of white light (containing all the wavelengths of visible light) falls on a pigment, certain wavelengths are absorbed. The remaining wavelengths are scattered or transmitted and make the pigment appear to us as colored. For example, the pigment **chlorophyll** absorbs both blue and red light, and we see the remaining light, which is primarily green. If we plot light absorbed by a purified pigment against wavelength, the result is an **absorption spectrum** for that pigment.

chlorophyll (klor' o fill) [Gk. *kloros*: green + *phyllon*: leaf] Any of several green pigments associated with chloroplasts or with certain bacterial membranes; responsible for trapping light energy for photosynthesis.

absorption spectrum A graph of light absorption versus wavelength of light; shows how much light is absorbed at each wavelength.

In contrast to the absorption spectrum, an **action spectrum** is a plot of the rate of photosynthesis carried out by an organism against the wavelengths of light to which it is exposed. An action spectrum for photosynthesis can be determined as follows:

action spectrum A graph of a biological process versus light wavelength; shows which wavelengths are involved in the process.

- . Place the organism in a closed container.
- . Expose it to light of a certain wavelength for a period of time.
- . Measure the rate of photosynthesis by the amount of O₂ released.
- . Repeat with light of other wavelengths.

Figure 10.4 shows the absorption spectra of pigments in *Anacharis*, a common aquarium plant, and the action spectrum for photosynthesis by that plant. The two spectra can be compared to see which pigments in *Anacharis* contribute most to light harvesting for photosynthesis.

(A) The absorption spectra of *Anacharis*

(B) The action spectrum for *Anacharis*

Figure 10.4 Absorption and Action Spectra (A) The absorption spectra of purified pigments from the common aquarium plant *Anacharis*. (B) The action spectrum for photosynthesis of that plant.

Q: Phycobilins are pigments that absorb yellow light. These pigments can transfer their absorbed energy to chlorophyll. How does this occur, thermodynamically?

The major pigment used to drive the light reactions of oxygenic photosynthesis is chlorophyll *a*. (In [Figure 10.4](#) you can see that the wavelengths at which photosynthesis is highest in *Anacharis* are the same wavelengths at which chlorophyll *a* absorbs the most light.) Chlorophyll *a* has a complex ring structure ([Figure 10.5](#)), similar to that of the heme group of hemoglobin, with a magnesium ion at the center. A long hydrocarbon “tail” anchors the molecule to proteins within a large multi-protein complex called a [photosystem](#), which spans the thylakoid membrane. Molecules of chlorophyll *a* and various accessory pigments (such as chlorophylls *b* and *c*, carotenoids, and phycobilins; see below) are arranged into [light-harvesting complexes](#), also called antenna systems. Multiple light-harvesting complexes surround a single [reaction center](#) within the photosystem.

photosystem [Gk. *phos*: light + *systema*: assembly] A light-harvesting complex in the chloroplast thylakoid composed of pigments and proteins. **Photosystem I** absorbs light at 700 nm, passing electrons to ferredoxin and from there to NADPH. **Photosystem II** absorbs light at 680 nm and passes electrons to the electron transport chain in the chloroplast.

light-harvesting complex In photosynthesis, a group of different molecules that cooperate to absorb light energy and transfer it to a reaction center. Also called antenna system.

reaction center A group of electron transfer proteins that receive energy from light-absorbing pigments and convert it to chemical energy by redox reactions.

Light energy is captured by the light-harvesting complexes and transferred to the reaction center, where chlorophyll a molecules participate in redox reactions that convert the light energy to chemical energy.

Chlorophyll absorbs blue and red light, which are near the two ends of the visible spectrum (see [Figure 10.3](#)). The various accessory pigments absorb light in other parts of the spectrum and thus function to broaden the range of wavelengths that can be used for photosynthesis. You can see this in the action spectrum in [Figure 10.4B](#): *Anacharis* is able to photosynthesize at wavelengths of light that chlorophyll *a* doesn't absorb but that other pigments absorb (e.g., 500 nanometers [nm]). Different photosynthetic organisms have different combinations of accessory pigments. Higher plants and green algae have chlorophyll *b* (with a structure and absorption spectrum very similar to that of chlorophyll *a*) and carotenoids such as β -carotene, which absorb photons in the blue and blue-green wavelengths. Phycobilins, which are found in red algae and cyanobacteria, absorb various yellow-green, yellow, and orange wavelengths.

Light absorption results in photochemical change

When a pigment molecule absorbs light, it enters an excited state. This is an unstable situation, and the molecule rapidly returns to its ground state, releasing most of the absorbed energy. So rapid is this process that it is measured in picoseconds (trillionths of a second). Within the antennae system of a photosystem ([Figure 10.6A](#)), the energy released by a pigment molecule (for example, chlorophyll *b*) is absorbed by other, adjacent pigment molecules. The energy (not as electrons but in the form of chemical energy called resonance) is passed from molecule to molecule until it reaches a chlorophyll *a* molecule at the reaction center of the photosystem ([Figure 10.6B](#)).

(A) A light-harvesting complex

(B) A phototsystem

Figure 10.6 Energy Transfer and Electron Transport (A) The molecular structure of a single light-harvesting complex shows the polypeptide in brown with three helices that span the thylakoid membrane. Pigment molecules (carotenoids and chlorophylls a and b) are bound to the polypeptide. **(B)** This simplified illustration of the entire photosystem uses chlorophyll molecules to represent the light-harvesting complexes. Energy from a photon is transferred from one pigment molecule to another, until it reaches a chlorophyll a molecule in the reaction center. The chlorophyll a molecule can give up its excited electron to an electron acceptor.

A ground-state chlorophyll a molecule at the reaction center (symbolized by Chl) absorbs the energy from the adjacent chlorophylls and becomes excited (Chl*), but to return to the ground state this chlorophyll does not pass the energy to another pigment molecule—something very different occurs. *The reaction center converts the absorbed light energy into chemical energy (Figure 10.7).* The chlorophyll molecule in the reaction center absorbs sufficient energy that it actually *gives up its excited electron to a chemical acceptor*:

Figure 10.7 Noncyclic Electron Transport Uses Two Photosystems Absorption of light energy by chlorophyll molecules in the reaction centers of photosystems I and II allows them to pass electrons into a series of redox reactions.

Q: An herbicide can act as an electron acceptor, becoming reduced by ferredoxin (Fd). What effect would this have on a plant?

This, then, is the first consequence of light absorption by chlorophyll: *the reaction center chlorophyll (Chl*) loses its excited electron in a redox reaction and becomes Chl+*. As a result of this transfer of an electron, the chlorophyll gets oxidized, while the acceptor molecule is reduced.

Reduction leads to ATP and NADPH formation

The electron acceptor that is reduced by Chl* is the first in a chain of electron carriers in the thylakoid membrane. Electrons are passed from one carrier to another in an energetically “downhill” series of reductions and oxidations. The final electron acceptor is NADP⁺, which gets reduced:

As in mitochondria, ATP is produced chemiosmotically in the thylakoid membrane during the process of photophosphorylation, which we will illustrate shortly. The overall process involves two **electron transport** processes, noncyclic and cyclic. The **noncyclic electron transport** reactions that use the energy from light to generate ATP and NADPH are illustrated in [Figure 10.7](#).

noncyclic electron transport In photosynthesis, the flow of electrons that forms ATP, NADPH, and O₂.

As seen in [Figure 10.7](#), two coordinated photosystems, each with its own reaction center, collaborate to produce ATP and NADPH:

- **Photosystem I** (containing the “P₇₀₀” chlorophylls at its reaction center) absorbs light energy best at 700 nm and passes its excited electrons (via intermediate molecules) to NADP⁺,

reducing it to NADPH.

- **Photosystem II** (with “P₆₈₀” chlorophylls at its reaction center) absorbs light energy best at 680 nm, oxidizes water molecules, and passes its energized electrons through a series of carriers to produce ATP.

photosystem I See photosystem.

photosystem II See photosystem.

Let's look in more detail at these photosystems, beginning with photosystem II.

PHOTOSYSTEM II

After an excited chlorophyll in the reaction center (Chl*) gives up its energetic electron to reduce a chemical acceptor molecule, the chlorophyll lacks an electron and is very unstable. It has a strong tendency to obtain an electron from another molecule to replace the one it lost—in chemical terms, it is a strong oxidizing agent. The replenishing electrons come from water, splitting the H—O—H bonds:

Notice that the source of O₂ in photosynthesis is H₂O (as demonstrated in Investigating Life: What is the chemistry of photosynthesis, and how will increasing CO₂ in the atmosphere affect it?).

Back to the electron acceptor in the electron transport system: the energetic electrons are passed through a series of membrane-bound carriers to a final acceptor at a lower energy level. As in the mitochondrion, a proton gradient is generated and is used by ATP synthase to make ATP (see below).

PHOTOSYSTEM I

In photosystem I, an excited electron from the Chl* at the reaction center reduces an acceptor. The oxidized chlorophyll (Chl⁺) now obtains an electron, but in this case the electron comes from the last carrier in the electron transport system. This links the two photosystems chemically. They are also linked spatially, with the two photosystems adjacent to one another in the thylakoid membrane. The energetic electrons from photosystem I pass through several molecules and end up reducing NADP⁺ to NADPH.

Next in the process of harvesting light energy to produce carbohydrates is the series of carbon-fixation reactions. These reactions require more ATP than NADPH. If the pathway we just described—the linear or noncyclic pathway—were the only set of light reactions operating, there might not be sufficient ATP for carbon fixation. **Cyclic electron transport** makes up for this imbalance. This pathway uses photosystem I and the electron transport system to produce ATP but not NADPH; it is cyclic because an electron is passed from an excited chlorophyll and recycles back to the same chlorophyll (**Figure 10.8**).

cyclic electron transport In photosynthetic light reactions, the flow of electrons that

produces ATP but not NADPH or O₂.

Figure 10.8 Cyclic Electron Transport Traps Light Energy as ATP

Chemiosmosis is the source of the ATP produced in photophosphorylation

In [Chapter 9](#) you learned about the chemiosmotic mechanism for ATP formation in the mitochondrion. A similar mechanism, called [photophosphorylation](#), operates in the chloroplast, where electron transport is coupled to the transport of protons (H⁺) across the thylakoid membrane, resulting in a proton gradient across the membrane ([Figure 10.9](#)).

photophosphorylation Mechanism for ATP formation in chloroplasts in which electron transport is coupled to the transport of hydrogen ions (protons, H⁺) across the thylakoid membrane. (Compare with chemiosmosis.)

Figure 10.9 Photophosphorylation In the thylakoid membrane, electrons are passed from photosystem II to photosystem I via a series of electron carriers, including plastoquinone (PQ), cytochrome (Cyt), and plastocyanin (PC). From photosystem I the electrons are passed to ferredoxin (Fd) and then to NADP⁺ reductase. This process results in a proton gradient across the membrane, which drives ATP synthesis. Compare this illustration with [Figure 9.8](#), where a similar process is depicted in mitochondria.

 Animation 10.2 **Photophosphorylation** www.Life11e.com/a10.2

The electron carriers in the thylakoid membrane are oriented so that protons are transferred from the stroma into the lumen of the thylakoid. Thus the lumen becomes more acidic (higher concentration of protons) compared with the stroma, resulting in an electrochemical gradient across the thylakoid membrane, whose bilayer is not permeable to H⁺. Water oxidation creates more H⁺ in the thylakoid lumen, and NADP⁺ reduction removes H⁺ in the stroma. Both reactions contribute to the H⁺ gradient. The high concentration of H⁺ in the thylakoid space drives the movement of H⁺ back into the stroma through protein channels in the membrane. These channels are also enzymes—ATP synthases—that couple the movement of protons to the formation of ATP, as they do in mitochondria (see [Figure 9.8](#)). Indeed, the amino acid sequence of chloroplast ATP synthase is about 60 percent identical to human mitochondrial ATP synthase—a remarkable similarity, given that plants and animals had their most recent common ancestor more than a billion years ago. This is testimony to the evolutionary unity of life.

The mechanisms of the two enzymes are similar, but their orientations differ. In chloroplasts, protons flow through the ATP synthase out of the thylakoid lumen into the stroma (where the ATP is synthesized). In mitochondria, the protons flow out of the intermembrane space into the mitochondrial matrix.

10.2 recap

Conversion of light energy into chemical energy occurs when photons are absorbed by chlorophylls and accessory pigments in the light-harvesting complex within the chloroplast. Light energy is used to drive a series of protein-associated redox reactions in the thylakoid membranes of the chloroplast. In the process of photophosphorylation, two linked photosystems establish a proton gradient across the membrane that drives ATP synthesis.

learning outcomes

You should be able to:

- Describe the transfer of energy within the reaction center of a light-harvesting complex.
- Compare and contrast a pigment's absorption spectrum and its action spectrum.
- Explain how ATP and NADPH are produced in a chloroplast.

-
1. How can a pigment molecule lose the energy of an absorbed photon?
 2. What is the difference between an absorption spectrum and an action spectrum?
 3. How does cyclic electron transport in photosystem I result in the production of ATP?

You have seen how light energy drives the synthesis of ATP and NADPH in the stroma of chloroplasts. We will now turn to the light-independent reactions of photosynthesis, which use energy-rich ATP and NADPH to reduce CO₂ and form carbohydrates.

*** connect the concepts** As discussed in [Key Concept 2.1](#), the electrons orbiting an atom are distributed in a series of electron shells, or energy levels, around the nucleus. The farther an electron is from the nucleus, the higher its energy level.

*** connect the concepts** The thylakoid membrane has an electron transport system similar to the respiratory chain of mitochondria (see [Key Concept 9.3](#)).

10.3

Chemical Energy Trapped in Photosynthesis Is Used to Synthesize Carbohydrates

Most of the enzymes that catalyze the reactions of CO₂ fixation are in the stroma of the chloroplast, where those reactions take place. These enzymes use the energy in ATP and NADPH to reduce CO₂ to carbohydrates. Therefore, with some exceptions, CO₂ fixation occurs only in the light, when ATP and NADPH are being generated.

focus your learning

The Calvin cycle describes the chemical steps that produce carbohydrates from carbon dioxide in the stroma of the chloroplast.

Light affects photosynthetic carbon fixation.

How were the steps in carbohydrate synthesis elucidated?

To identify the reactions by which the carbon from CO₂ ends up in carbohydrates, scientists found a way to label CO₂ so they could isolate and identify the compounds formed from it during photosynthesis. In the 1950s, Melvin Calvin, Andrew Benson, and their colleagues used radioactively labeled CO₂ in which some of the carbon atoms were the radioisotope ¹⁴C rather than the normal ¹²C. They were able to trace the chemical pathway of CO₂ fixation ([Figure 10.10](#)). The first molecule that appeared in the pathway was a three-carbon sugar phosphate called 3-phosphoglycerate (3PG) (the ¹⁴C is shown in red):

Figure 10.10A Tracing the Pathway of CO₂

Original Papers: Calvin and his colleagues described their experiments in a series of 26 papers titled "The Path of Carbon in Photosynthesis." Perhaps the most important was one that showed how labeled CO₂ could be used as a tracer:

Benson, A. A., J. A. Bassham, M. Calvin, T. C. Goodale, V. A. Haas and W. Stepka. 1950. The path of carbon in photosynthesis. V. Paper chromatography and radioautography of the products. *Journal of the American Chemical Society* 72: 1710–1718.

How is CO₂ incorporated into carbohydrate during photosynthesis? What is the first stable covalent linkage that forms with the carbon of CO₂? Melvin Calvin and his colleagues used short exposures to ¹⁴CO₂ to identify the first compound formed from CO₂.

HYPOTHESIS ▶ The first product of CO₂ fixation is a 3-carbon molecule.

METHOD

The algal extract was applied here as a spot and run in two directions to separate compounds from one another.

After separation of the compounds, the chromatogram was overlaid with X-ray film. Radioactive compounds show up as dark spots.

RESULTS

A chromatogram made after 3 seconds of exposure to ¹⁴CO₂ shows ¹⁴C only in 3PG (3-phosphoglycerate).

A chromatogram made after 30 seconds of exposure to ¹⁴CO₂ shows ¹⁴C in many molecules.

CONCLUSION ▶ The initial product of CO₂ fixation is 3PG. Later, the carbon from CO₂ ends up in many molecules.

work with the data

Figure 10.10B Tracing the Pathway of CO₂

Original Paper: Benson, A. A. et al. 1950.

To elucidate the sequence of reactions that allow carbon fixation, Melvin Calvin and colleagues exposed suspensions of the green alga *Chlorella* to ¹⁴CO₂ (see Figure 10.10A). After 3 sec of photosynthesis, the ¹⁴C from ¹⁴CO₂ was found only in 3-phosphoglycerate (3PG), but after 30 sec many compounds were radioactive. Calvin and his colleagues then expanded on these results and were able to determine the exact sequence of reactions and reaction intermediates in the Calvin cycle by exposing the cells to ¹⁴CO₂ for various periods of time.

The first reaction in CO₂ fixation can occur in the dark. To show this, Calvin and his colleagues exposed *Chlorella* cells to ¹⁴CO₂ under bright lights for 20 min and harvested the cells. Then they repeated the experiment, but following the 20 min of light with varying periods of darkness (30 sec, 2 min, and 5 min). They harvested cells and made chromatograms to identify the labeled compounds, and used a radioactivity detector to quantify the amount of ¹⁴C in each compound. The data are shown in the table.

Compound	Relative amount of radioactivity after:			
	20 min light	20 min light + 30 sec dark	20 min light + 2 min dark	20 min light + 5 min dark
3PG	5,500	10,100	10,000	5,200
RuBP	4,900	680	1,850	1,800
Sucrose	13,000	13,500	15,000	14,750

QUESTIONS

1. Plot radioactivity in 3PG versus time. What do the data show?
2. Why did the amount of radioactively labeled RuBP decline after 30 seconds in the dark?

A similar **work with the data** exercise may be assigned in **LaunchPad**

Animation 10.3 Tracing the Pathway of CO₂ www.Life11e.com/a10.3

Using successively longer exposures to ¹⁴CO₂, Calvin and his colleagues were able to trace the route of ¹⁴C as it moved through a series of compounds, including monosaccharides and amino acids. It turned out the ¹⁴C moved through a cyclical pathway. In this cycle, the CO₂ initially bonds covalently to a five-carbon acceptor molecule. The resulting six-carbon intermediate quickly breaks into two three-carbon molecules. As the cycle repeats, a carbohydrate is produced and the initial CO₂ acceptor is regenerated. This pathway was appropriately named the **Calvin cycle**.

Calvin cycle The stage of photosynthesis in which CO₂ reacts with RuBP to form 3PG, 3PG is reduced to a sugar, and RuBP is regenerated, while other products are released to the rest of the plant. Also known as the Calvin–Benson cycle.

The initial reaction in the Calvin cycle adds the one-carbon CO₂ to the five-carbon acceptor molecule ribulose 1,5-bisphosphate (RuBP). The product is an intermediate six-carbon compound, which quickly breaks down and forms two molecules of 3PG (**Figure 10.11**). The intermediate compound is broken down so rapidly that Calvin did not observe radioactive carbon appearing in it first. The enzyme that catalyzes its formation, **ribulose bisphosphate carboxylase/oxygenase (rubisco)**, is the most abundant protein in the world! It constitutes up to 50 percent of all the protein in every plant leaf.

Figure 10.11 RuBP Is the Carbon Dioxide Acceptor CO_2 is added to a five-carbon compound, RuBP. The resulting six-carbon compound immediately splits into two molecules of 3PG.

ribulose biphosphate carboxylase/oxygenase See rubisco.

rubisco Contraction of ribulose biphosphate carboxylase/oxygenase, the enzyme that combines carbon dioxide or oxygen with ribulose biphosphate to catalyze the first step of photosynthetic carbon fixation or photorespiration, respectively.

The Calvin cycle is made up of three processes

The Calvin cycle uses the ATP and NADPH made in the light to reduce CO_2 in the stroma to a carbohydrate. As in all biochemical pathways, each reaction is catalyzed by a specific enzyme. The cycle is composed of three distinct processes ([Figure 10.12](#)):

Figure 10.12 The Calvin Cycle The Calvin cycle uses the ATP and NADPH generated in the light reactions and CO₂ to produce carbohydrate. Six turns of the cycle produce the equivalent of one molecule of glucose, a hexose sugar.

Activity 10.1 The Calvin Cycle www.Life11e.com/ac10.1

- **Fixation** of CO₂. As we have seen, this reaction is catalyzed by rubisco, and its stable product is 3PG.
- **Reduction** of 3PG to form glyceraldehyde 3-phosphate (G3P). This series of reactions involves a phosphorylation (using the ATP made in the light reactions) and a reduction (coupled to the oxidation of NADPH made in the light reactions).
- **Regeneration** of the CO₂ acceptor, RuBP. Most of the G3P ends up as ribulose monophosphate (RuMP), and ATP is used to convert this compound into RuBP. So for every “turn” of the cycle, one CO₂ is fixed and one CO₂ acceptor is regenerated.

The product of this cycle is **glyceraldehyde 3-phosphate (G3P)**, which is a three-carbon sugar phosphate, also called triose phosphate:

glyceraldehyde 3-phosphate (G3P) A phosphorylated three-carbon sugar; an intermediate in glycolysis and photosynthetic carbon fixation.

Glyceraldehyde 3-phosphate (G3P)

In a typical leaf, five-sixths of the G3P is recycled into RuBP. There are two fates for the remaining G3P, depending on the time of day and the needs of different parts of the plant:

- Some of the G3P is exported out of the chloroplast to the cytoplasm, where it is converted to hexoses (glucose and fructose). These molecules may be used in glycolysis and mitochondrial respiration to power the activities of photosynthetic cells (see [Chapter 9](#)) or they may be converted into the disaccharide sucrose, which is transported out of the leaf to other organs in the plant. There the sucrose is hydrolyzed to its constituent monosaccharides, which can be used as sources of energy or as building blocks for other molecules.
- Some of the G3P is used to synthesize glucose inside the chloroplast. As the day wears on, glucose molecules accumulate and are linked together to form the polysaccharide starch. This stored carbohydrate can then be drawn on during the night so that the photosynthetic tissues can continue to export sucrose to the rest of the plant, even when photosynthesis is not taking place. In addition, starch is abundant in nonphotosynthetic organs such as roots, underground stems, and seeds, where it provides glucose to fuel cellular activities, including plant growth.

The plant uses the carbohydrates produced in photosynthesis to make other molecules, including amino acids, lipids, and the building blocks of nucleic acids—in fact, all the organic molecules in the plant.

The products of the Calvin cycle are of crucial importance to Earth's entire biosphere. For the majority of living organisms on Earth, the C—C and C — H covalent bonds generated by the cycle provide almost all of the energy for life. Photosynthetic organisms, which are also called **autotrophs** ("self-feeders"), release most of this energy by glycolysis and cellular respiration, and use it to support their own growth, development, and reproduction. But plants are also the source of energy for other organisms. Much plant matter ends up being consumed by **heterotrophs** ("other-feeders"), such as animals, including you, which cannot photosynthesize. Heterotrophs depend on autotrophs for both raw materials and energy. Free energy is released from food by glycolysis and cellular respiration in the cells of heterotrophs.

autotroph (au' tow trowf) [Gk. *autos*: self + *trophe*: food] An organism that is capable of living exclusively on inorganic materials, water, and some energy source such as sunlight (photoautotrophs) or chemically reduced matter (see chemoautotrophs). (Contrast with heterotroph.)

heterotroph (het' er oh trof) [Gk. *heteros*: different + *trophe*: feed] An organism that requires preformed organic molecules as food. (Contrast with autotroph.)

Light stimulates the Calvin cycle

As you have seen, the Calvin cycle uses NADPH and ATP, which are generated using energy from light. Two other processes connect the light reactions with this CO₂ fixation pathway. Both connections are indirect but significant:

- *Light-induced pH changes in the stroma activate some Calvin cycle enzymes.* Proton transfer from the stroma into the thylakoid lumen causes an increase in the pH of the stroma from 7 to 8 (a tenfold decrease in H⁺ concentration) that favors the activation of rubisco.
- *Light-induced electron transport reduces disulfide bridges in four of the Calvin cycle enzymes, thereby activating them (Figure 10.13).* When ferredoxin is reduced in photosystem I (see Figure 10.7), it passes some electrons to a small, soluble protein called thioredoxin, and this protein passes electrons to four enzymes in the CO₂ fixation pathway. Reduction of the sulfurs in the disulfide bridges of these enzymes (see Figure 3.5) forms SH groups and breaks the bridges. The resulting changes in their three-dimensional shapes activate the enzymes and increase the rate at which the Calvin cycle operates.

Figure 10.13 The Photochemical Reactions Stimulate the Calvin Cycle By reducing (breaking) disulfide bridges, electrons from the light reactions activate enzymes in CO₂ fixation.

ATP and NADPH produced in the light reactions power the synthesis of carbohydrates by the Calvin cycle. This cycle fixes CO₂, reduces it, and regenerates the acceptor, RuBP, for further fixation.

learning outcomes

You should be able to:

- Describe the experiment that led to identification of the steps in the Calvin cycle.
- Explain how light reactions stimulate the Calvin cycle.

-
1. What experiments led to the identification of 3PG as the initial product of carbon fixation?
 2. In what ways does light stimulate the Calvin cycle?
 3. Both photosynthetic electron transport and the Calvin cycle stop in the dark. Which specific reaction stops first? Which stops next? Continue answering the question “Which stops next?” until you have explained why both pathways have stopped.

Although all green plants carry out the Calvin cycle, some plants have evolved variations on, or additional steps in, the light-independent reactions. These variations and additions have permitted plants to adapt to and thrive in certain environmental conditions. Let's look at these environmental limitations and the metabolic bypasses that have evolved to circumvent them.

10.4 Plants Have Adapted Photosynthesis to Environmental Conditions

In addition to fixing CO_2 during photosynthesis, rubisco can react with O_2 . This reaction, which leads to a process called photorespiration, lowers the overall rate of CO_2 fixation in some plants. After examining this problem, we'll look at some biochemical pathways and features of plant anatomy that compensate for the limitations of rubisco.

focus your learning

C_4 plants have evolved to avoid photorespiration under hot, dry conditions, whereas C_3 plants have not.

CAM plants differ from C_4 plants by separating carbon fixation from the Calvin cycle according to different times of the day.

How do some plants overcome the limitations of CO_2 fixation?

As its full name indicates, rubisco (ribulose biphosphate carboxylase/oxygenase) is an **oxygenase** as well as a **carboxylase**—it can add O_2 or CO_2 , respectively, to the acceptor molecule RuBP:

oxygenase An enzyme that catalyzes the addition of oxygen to a substrate from O_2 .

carboxylase An enzyme that catalyzes the addition of carboxyl functional groups ($\text{O}=\text{C}-\text{OH}$) to a substrate.

Rubisco is a carboxylase when it adds CO_2 to RuBP.

Rubisco is an oxygenase when it adds O_2 to RuBP.

Think about the concentrations of O_2 and CO_2 in the typical air that you breathe. The concentration of CO_2 in Earth's atmosphere is about 400 ppm, or 0.04%. The concentration of O_2 in the air is about 20%. You would think that if there were an "even competition" between CO_2 and O_2 for rubisco that the latter, with its higher concentration, would be favored. But such is not the case. It turns out that the affinity (binding) of rubisco for CO_2 is much stronger than it is for O_2 , so in normal air inside a leaf, CO_2 fixation is favored even though the concentration of CO_2 in the air is far lower than that of O_2 . It is when there is an even higher concentration of O_2 in the leaf relative to outside that O_2 competes with the CO_2 , and rubisco combines RuBP with O_2 rather than with CO_2 . This oxygenase activity reduces the overall amount of CO_2 that can be converted into carbohydrates, and may play a role in limiting plant growth.

Relatively low O_2 and high CO_2 concentrations within the leaf favor carboxylase activity.

Relatively high O_2 and low CO_2 concentrations within the leaf favor oxygenase activity.

Under what conditions inside the leaf does the air have higher O_2 and lower CO_2 , favoring the oxygenase activity? On a hot, dry day, small pores in the leaf surface called **stomata** close to

prevent water from evaporating from the leaf (see [Figure 10.1](#)). But stomata closure also prevents gases from entering and leaving the leaf. If stomata are closed, the CO₂ concentration in the leaf falls as CO₂ is used up in photosynthetic reactions, and the O₂ concentration rises because of these same reactions where water is used to form O₂ (see Investigating Life: What is the chemistry of photosynthesis, and how will increasing CO₂ in the atmosphere affect it?). As the ratio of CO₂ to O₂ falls, the oxygenase activity of rubisco is favored.

stoma (plural: stomata) [Gk. *stoma*: mouth, opening] Small opening in the plant epidermis that permits gas exchange; bounded by a pair of guard cells whose osmotic status regulates the size of the opening.

The consequences of oxygenase activity and lower carboxylase activity are significant. When O₂ is added to RuBP, one of the products is a two-carbon compound, phosphoglycolate:

The 3PG formed by rubisco's oxygenase activity enters the Calvin cycle, but the phosphoglycolate does not. Plants have evolved a metabolic pathway that can partially recover the carbon in phosphoglycolate. The phosphoglycolate is hydrolyzed to glycolate, which diffuses into peroxisomes ([Figure 10.14](#)). There, a series of reactions converts it into the amino acid glycine:

(A) The organelles of photorespiration

(B) Two catalytic activities of rubisco

Figure 10.14 The Photorespiration Pathway (A) The reactions of photorespiration take place in the chloroplasts, peroxisomes, and mitochondria. (B) Overall, photorespiration consumes O₂ and releases CO₂.

Media Clip 10.1 Chloroplasts in Close-Up W www.Life11e.com/mc10.1

The glycine then diffuses into a mitochondrion, where two glycine molecules are converted in a series of reactions into the amino acid serine, releasing CO₂:

The serine moves into the peroxisome, where it is converted to glycerate. The glycerate then moves into the chloroplast, where it is phosphorylated to make 3PG, which enters the Calvin cycle. Note that it takes two phosphoglycolate molecules from [Equation 10.11](#) to produce the two glycines used in [Equation 10.13](#). So overall:

This pathway thus reclaims 75 percent of the carbons from phosphoglycolate for the Calvin cycle. In other words, the reaction of RuBP with O₂ instead of CO₂ *reduces the net carbon fixed by the Calvin cycle by 25 percent*. The pathway is called **photorespiration** because it consumes O₂ and releases CO₂ and because it occurs only in the light (mediated by the same enzyme activation processes that we mentioned above with regard to the Calvin cycle).

photorespiration Light-driven uptake of oxygen and release of carbon dioxide, the carbon being derived from the early reactions of photosynthesis.

Activity 10.2 C₃ and C₄ Leaf Anatomy www.Life11e.com/ac10.2

C₃ plants undergo photorespiration but C₄ plants do not

Plants differ in how they fix CO₂, and can be distinguished as C₃ or C₄ plants, based on whether the first product of CO₂ fixation is a three- or four-carbon molecule. In **C₃ plants** such as roses, wheat, and rice, the first product is the three-carbon molecule 3PG—as we have just described for the Calvin cycle. In these plants the cells of the mesophyll, which makes up the main body of the leaf, are full of chloroplasts containing rubisco (**Figure 10.15A**). On a hot day, these leaves close their stomata to conserve water, and as a result, rubisco acts as an oxygenase as well as a carboxylase, and photorespiration occurs.

C₃ plants Plants that produce 3PG as the first stable product of carbon fixation in photosynthesis and use ribulose biphosphate as a CO₂ receptor.

(A) Arrangement of cells in a C₃ leaf

(B) Arrangement of cells in a C₄ leaf

Figure 10.15 Leaf Anatomy of C₃ and C₄ Plants Carbon dioxide fixation occurs in different organelles and cells of the leaves in (A) C₃ plants and (B) C₄ plants. Cells that are tinted blue have rubisco.

C₄ plants, which include corn, sugarcane, and tropical grasses, make the four-carbon molecule **oxaloacetate** as the first product of CO₂ fixation (**Figure 10.15B**). On a hot day, they partially close their stomata to conserve water, but their rate of photosynthesis does not fall.

What do they do differently?

C₄ plants Plants that produce oxaloacetate as the first stable product of carbon fixation in photosynthesis and use phosphoenolpyruvate as a CO₂ acceptor. C₄ plants also perform the reactions of C₃ photosynthesis.

oxaloacetate Four-carbon salt of an acid with the formula HOOC—CO—CO—COOH that is an intermediate in metabolic pathways such as the citric acid cycle.

C₄ plants have evolved a mechanism that increases the concentration of CO₂ around the rubisco enzyme while at the same time isolating the rubisco from atmospheric O₂. Thus in these plants the carboxylase reaction is favored over the oxygenase reaction; the Calvin cycle operates, but photorespiration does not occur. This mechanism involves the initial fixation of CO₂ in the mesophyll cells and then the transfer of the fixed carbon (as a four-carbon molecule) to the **bundle sheath cells**, where the fixed CO₂ is released for use in the Calvin cycle (**Figure 10.16**). The bundle sheath cells are located in the interior of the leaf where less atmospheric O₂ can reach them than reaches cells near the surface of the leaf.

bundle sheath cell Part of a tissue that surrounds the veins of plants.

(B)

Figure 10.16 The Anatomy and Biochemistry of C₄ Carbon Fixation (A) Carbon dioxide is fixed initially in the mesophyll cells but enters the Calvin cycle in the bundle sheath cells. (B) The two cell types share an interconnected biochemical pathway for CO₂ assimilation.

The first enzyme in this C₄ carbon fixation process, called **PEP carboxylase**, is present in the cytosols of mesophyll cells near the leaf's surface. This enzyme combines CO₂ with a three-carbon acceptor compound, **phosphoenolpyruvate (PEP)**, to produce the four-carbon fixation product, oxaloacetate. PEP carboxylase has two advantages over rubisco:

PEP carboxylase The enzyme that combines carbon dioxide with PEP to form a 4-carbon dicarboxylic acid at the start of C₄ photosynthesis or of crassulacean acid metabolism (CAM).
phosphoenolpyruvate (PEP) Phosphorylated salt of a three-carbon acid, formula $\text{OPO}_3\text{H}_2\text{—CO—CO—COOH}$ that is an intermediate in metabolic pathways such as glycolysis.

- . It does not have oxygenase activity.
- . It fixes CO₂ even at very low CO₂ levels.

So even on a hot day when the stomata are partially closed and the ratio of O_2 to CO_2 rises, PEP carboxylase just keeps on fixing CO_2 .

Oxaloacetate is converted to malate, which diffuses out of the mesophyll cells and into the bundle sheath cells (see [Figure 10.15B](#)). (Some C_4 plants convert the oxaloacetate to aspartate instead of malate, but we will only discuss the malate pathway here.) The bundle sheath cells contain modified chloroplasts that are designed to concentrate CO_2 around the rubisco. There, the four-carbon malate loses one carbon (is decarboxylated), forming CO_2 and pyruvate. The latter moves back to the mesophyll cells where the three-carbon acceptor compound, PEP, is regenerated at the expense of ATP. So the “expenditure” of ATP in the mesophyll cell “pumps up” the CO_2 concentration around rubisco in the bundle sheath cell, ensuring that rubisco will function as a carboxylase and begin the Calvin cycle.

Under relatively cool or cloudy conditions, C_3 plants have an advantage over C_4 plants in that they don’t expend energy to “pump up” the concentration of CO_2 near rubisco. But this advantage begins to be outweighed under conditions that favor photorespiration, such as warmer seasons and climates. Under these conditions C_4 plants have the advantage, especially if there is ample light to supply the extra ATP required for C_4 photosynthesis. For example, Kentucky bluegrass is a C_3 plant that thrives on lawns in April and May. But in the heat of summer it does not do as well, and Bermuda grass, a C_4 plant, takes over the lawn. The same is true on a global scale for crops: C_3 plants such as soybean, wheat, and barley have been adapted for human food production in temperate climates, whereas C_4 plants such as corn and sugarcane originated and are still grown in the tropics.

THE EVOLUTION OF CO_2 FIXATION PATHWAYS

C_3 plants are more ancient than C_4 plants. Whereas C_3 photosynthesis appears to have begun about 2.5 billion years ago, C_4 plants appeared about 12 million years ago. A possible factor in the emergence of the C_4 pathway is the decline in atmospheric CO_2 . When dinosaurs dominated Earth 100 million years ago, the concentration of CO_2 in the atmosphere was four times what it is now. As CO_2 levels declined thereafter, the C_4 plants would have gained an advantage over their C_3 counterparts in high-temperature, high-light environments.

As described in the opening of this chapter, atmospheric CO_2 levels have been increasing over the past 200 years. Currently, the level of CO_2 is not enough for maximal CO_2 fixation by rubisco, so photorespiration occurs, reducing the growth rates of C_3 plants. Under hot conditions, C_4 plants are favored. But if CO_2 levels in the atmosphere continue to rise, the reverse will occur and C_3 plants will have a comparative advantage. The overall growth rates of crops such as rice and wheat should increase. This may or may not translate into more food, given that other effects of the human-spurred CO_2 increase (such as global climate change) will also alter Earth’s ecosystems.

CAM plants also use PEP carboxylase

Other plants besides the C_4 plants use PEP carboxylase to fix and accumulate CO_2 . They include some water-storing plants (succulents) of the family Crassulaceae, many cacti, pineapples, and several other kinds of flowering plants. The CO_2 metabolism of these plants is called [crassulacean acid metabolism](#), or **CAM**, after the family of succulents in which it was discovered. CAM is much like the metabolism of C_4 plants in that CO_2 is initially fixed into a four-carbon compound. But in CAM plants the initial CO_2 fixation and the Calvin cycle are *separated in time rather than space*.

crassulacean acid metabolism (CAM) A metabolic pathway enabling the plants that
--

possess it to store carbon dioxide at night and then perform photosynthesis during the day with stomata closed.

CAM See crassulacean acid metabolism.

At night, when it is cooler and water loss is minimized, the stomata open. CO₂ is fixed in mesophyll cells to form the four-carbon compound oxaloacetate, which is converted into malate and stored in the vacuole.

During the day, when the stomata close to reduce water loss, the accumulated malate is shipped from the vacuole to the chloroplasts, where its decarboxylation supplies the CO₂ for the Calvin cycle and the light reactions supply the necessary ATP and NADPH.

10.4 recap

Rubisco catalyzes the carboxylation of RuBP to form two 3PG, and the oxygenation of RuBP to form one 3PG and one phosphoglycolate. The diversion of rubisco to its oxygenase function decreases net CO₂ fixation. C₄ photosynthesis and CAM allow plants to fix CO₂ under warm, dry conditions when stomata are closed and CO₂ entry into the leaf is limited.

learning outcomes

You should be able to:

- Explain how and why C₄ plants maintain a high concentration of CO₂ around rubisco.
- Explain how CAM plants carry out carbon fixation separately from Calvin cycle reactions.

1. How do C₄ plants keep the concentration of CO₂ around rubisco high, and why?
2. Describe CAM plants and explain how they can temporally segregate CO₂ fixation from the Calvin cycle.

Table 10.1 compares photosynthesis in C₃, C₄, and CAM plants. Now that you understand how photosynthesis produces carbohydrates, let's see how the pathways of photosynthesis are connected to other metabolic pathways.

table 10.1 Comparison of Photosynthesis in C ₃ , C ₄ , and CAM Plants					
	C ₃ plants		C ₄ plants		CAM plants
Calvin cycle used?	Yes		Yes		Yes 
Primary CO ₂ acceptor	RuBP		PEP		PEP
Primary CO ₂ -fixing enzyme	Rubisco		PEP carboxylase		PEP carboxylase
First product of CO ₂ fixation	3PG (3-carbon)		Oxaloacetate (4-carbon)		Oxaloacetate (4-carbon)
Affinity of primary fixing enzyme for CO ₂	Moderate		High		High

Photosynthetic cells of leaf	Mesophyll	Mesophyll and bundle sheath	Mesophyll with large vacuoles
Photorespiration	Extensive	Minimal	Minimal

10.5 Photosynthesis Is an Integral Part of Plant Metabolism

Green plants are autotrophs and can synthesize all the molecules they need from simple starting materials: CO_2 , H_2O , phosphate, sulfate, ammonium ions (NH_4^+), and small quantities of other mineral nutrients. Plants use the carbohydrates generated in photosynthesis to provide energy for processes such as active transport and anabolism. Both cellular respiration and fermentation can occur in plants, although the former is far more common. Unlike photosynthesis, plant cellular respiration occurs all the time in both the light and the dark.

focus your learning

Photosynthesis is linked to cellular respiration, gluconeogenesis, and other metabolic pathways.

Photosynthesis is responsible for providing the energy needed by most organisms on Earth.

Photosynthesis interacts with other metabolic pathways

Photosynthesis and respiration are closely linked through the Calvin cycle ([Figure 10.17](#)). The partitioning of G3P, the product of the Calvin cycle, is particularly important:

Figure 10.17 Metabolic Interactions in a Plant Cell The products of the Calvin cycle are used in the reactions of cellular respiration (glycolysis and the citric acid cycle).

Some G3P from the Calvin cycle enters glycolysis and is converted into pyruvate in the cytosol. This pyruvate can be used in cellular respiration for energy, or its carbon skeletons can be used in anabolic reactions to make lipids, proteins, and other carbohydrates (see [Figure 9.13](#)).

Some G3P can enter a pathway that is the reverse of glycolysis (gluconeogenesis; see [Key Concept 9.5](#)). In this case, hexose phosphates (hexose P) and then sucrose are formed and transported to the nonphotosynthetic tissues of the plant (such as the root).

Energy flows from sunlight to reduced carbon in photosynthesis, then to ATP in respiration. Energy can also be stored in the bonds of macromolecules such as polysaccharides, lipids, and proteins. For a plant to grow, energy storage (as body structures) must exceed energy release; that is, overall carbon fixation by photosynthesis must exceed respiration. This principle is the basis of the ecological ***food chain**, as you will see in later chapters.

Photosynthesis provides most of the energy that we need for life. Given the uncertainties about the future of photosynthesis (because of changes in CO₂ levels and climate change), it would be wise to seek ways to improve photosynthetic efficiency. **Figure 10.18** shows the various ways in which solar energy is used by plants or lost. In essence, only about 5 percent of the sunlight that reaches Earth is converted into plant growth. The inefficiencies of photosynthesis involve basic chemistry and physics (some light energy is not absorbed by photosynthetic pigments) as well as biology (plant anatomy and leaf exposure, the oxygenase reaction of rubisco, and inefficiencies in metabolic pathways). While it is hard to change chemistry and physics, biologists might be able to use their knowledge of plants to improve on the basic biology of photosynthesis. This could result in a more efficient use of resources and better food production.

Figure 10.18 Energy Losses in Photosynthesis Photosynthetic pathways preserve at most about 5 percent of the sun's energy input as chemical energy in carbohydrates.

10.5 recap

The products of photosynthesis are used in glycolysis and the citric acid cycle, as well as in the synthesis of lipids, proteins, and other large molecules.

learning outcomes

You should be able to:

- Identify the metabolic intermediates that link photosynthesis to other metabolic pathways.
- Explain the efficiency of energy flow as it moves from the environment through living organisms on Earth.

1. How do common intermediates link the pathways of glycolysis, the citric acid cycle, and photosynthesis?
2. Why is at most 5 percent of the solar radiation that reaches Earth converted to plant growth?

investigatinglife

QA What is the chemistry of photosynthesis, and how will it be affected by rising atmospheric CO₂?

Crops could be affected by increased atmospheric CO₂ in multiple ways. Higher CO₂ levels generally lead to increased photosynthesis. This is especially true for C₃ plants, which are more sensitive than C₄ plants to CO₂ levels. Because increased photosynthesis leads to greater plant growth, C₃ crops such as wheat and rice will tend to grow more. However, it is unclear whether this growth will be in the vegetative parts of the plant (stems and leaves) or in the part we eat (grain). To further complicate matters, such increases in plant growth may be counteracted by the effects of increased CO₂ on climate. For example, increased temperatures would increase the rate of photosynthesis and extend the growing season, but might alter rainfall patterns. In some areas of the world there might be less rain, and this could limit plant growth.

Future directions

As the human population rises and land for farming is limited, we are challenged to improve the productivity of crops. A significant increase in overall crop productivity would have global consequences. Increased atmospheric CO₂ will not have a great effect on C₄ plants. But the C₄ pathway accounts for about 25 percent of all net carbon fixed. Some important species, such as corn, sorghum, and sugarcane, have the C₄ pathway, but the major grain crops such as rice do not. An intensive research program is under way to understand the genetic control of the development of the C₄ pathway, including not just the enzymes involved but also how the distinctive leaf anatomy develops. This research may lead to greater use of the C₄ pathway, and its related increase in productivity in more plant species in a higher-CO₂ world.

► 10.1 Photosynthesis Uses Light to Make Carbohydrates

- In the process of photosynthesis, the energy of sunlight is captured and used to convert CO_2 into more complex carbon-containing compounds. **See [Animation 10.1](#)**
- Isotope-labeling experiments demonstrated that water is the source of the oxygen atoms in the O_2 produced by photosynthesis. **Review Investigating Life: What Is the Chemistry of Photosynthesis, and How Will Increasing CO_2 in the Atmosphere Affect It?**
- Plants, algae, and cyanobacteria live in aerobic environments and carry out oxygenic photosynthesis: the conversion of CO_2 and H_2O into carbohydrates and release of O_2 .
- Some bacteria that live in anaerobic environments carry out anoxygenic photosynthesis, in which energy from the sun is used to fix CO_2 without the use of H_2O and the production of O_2 .
- The **[light reactions](#)** of photosynthesis convert light energy into chemical energy in the form of ATP and NADPH. **Review Focus: Key [Figure 10.2](#)**

light reactions The initial phase of photosynthesis, in which light energy is converted into chemical energy.

- The **[light-independent reactions](#)** do not use light directly but instead use ATP and NADPH to reduce CO_2 , forming carbohydrates.

light-independent reactions Reactions that follow the light reaction and use the energy captured in the light reactions to drive the reduction of CO_2 to form carbohydrates.

► 10.2 Photosynthesis Converts Light Energy into Chemical Energy

- Light is a form of **[electromagnetic radiation](#)**. It is emitted in particle-like packets called **[photons](#)** but has wavelike properties.

electromagnetic radiation A self-propagating wave that travels through space and has both electrical and magnetic properties.

photon (foe' ton) [Gk. *photos*: light] A quantum of visible radiation; a "packet" of light energy.

- Molecules that absorb light in the visible spectrum are called **[pigments](#)**. Photosynthetic organisms have several pigments, most notably **[chlorophylls](#)**.

pigment A substance that absorbs visible light.

chlorophyll (klor' o fill) [Gk. *chloros*: green + *phyllon*: leaf] Any of several green pigments associated with chloroplasts or with certain bacterial membranes; responsible for trapping light energy for photosynthesis.

- Absorption of a photon puts an electron of a pigment molecule in an excited state that has more energy than its ground state.
- Each pigment has a characteristic [absorption spectrum](#). An [action spectrum](#) reflects the rate of photosynthesis carried out by a photosynthetic organism at a given wavelength of light. **Review [Figure 10.4](#)**

absorption spectrum A graph of light absorption versus wavelength of light; shows how much light is absorbed at each wavelength.

action spectrum A graph of a biological process versus light wavelength; shows which wavelengths are involved in the process.

- The pigments in photosynthetic organisms are arranged into [light-harvesting complexes](#) that absorb energy from light and funnel this energy to chlorophyll a molecules in the reaction center of the [photosystem](#). Chlorophyll can act as a reducing agent, transferring excited electrons to other molecules. **Review [Figure 10.6](#)**

light-harvesting complex In photosynthesis, a group of different molecules that cooperate to absorb light energy and transfer it to a reaction center. Also called antenna system.

photosystem [Gk. *phos*: light + *systema*: assembly] A light-harvesting complex in the chloroplast thylakoid composed of pigments and proteins. **Photosystem I** absorbs light at 700 nm, passing electrons to ferredoxin and from there to NADPH. **Photosystem II** absorbs light at 680 nm and passes electrons to the electron transport chain in the chloroplast.

- [Noncyclic electron transport](#) uses photosystems I and II to produce ATP, NADPH, and O₂. [Cyclic electron transport](#) uses only photosystem I and produces only ATP. Both systems generate ATP via the electron transport system. **Review [Figures 10.7](#), [10.8](#)**

noncyclic electron transport In photosynthesis, the flow of electrons that forms ATP, NADPH, and O₂.

cyclic electron transport In photosynthetic light reactions, the flow of electrons that produces ATP but not NADPH or O₂.

- Chemiosmosis is the mechanism of ATP production in [photophosphorylation](#). **Review [Figure 10.9](#), [Animation 10.2](#)**

photophosphorylation Mechanism for ATP formation in chloroplasts in which electron transport is coupled to the transport of hydrogen ions (protons, H⁺) across the thylakoid membrane. (Compare with chemiosmosis.)

► 10.3 Chemical Energy Trapped in Photosynthesis Is Used to Synthesize Carbohydrates

- The Calvin cycle makes carbohydrates from CO₂. The cycle consists of three processes: fixation of CO₂, reduction and carbohydrate production, and regeneration of RuBP. **See [Animation 10.3](#)**
- RuBP is the initial CO₂ acceptor, and 3PG is the first stable product of CO₂ fixation. The enzyme [ribulose biphosphate carboxylase/oxygenase](#) ([rubisco](#)) catalyzes the

reaction of CO_2 and RuBP to form 3PG. **Review** [Figures 10.10](#), [10.11](#)

ribulose biphosphate carboxylase/oxygenase See rubisco.

rubisco Contraction of ribulose biphosphate carboxylase/oxygenase, the enzyme that combines carbon dioxide or oxygen with ribulose biphosphate to catalyze the first step of photosynthetic carbon fixation or photorespiration, respectively.

- ATP and NADPH formed by the light reactions are used in the reduction of 3PG to form [glyceraldehyde 3-phosphate \(G3P\)](#). **Review** [Figure 10.12](#), [Activity 10.1](#)

glyceraldehyde 3-phosphate (G3P) A phosphorylated three-carbon sugar; an intermediate in glycolysis and photosynthetic carbon fixation.

- Light stimulates enzymes in the Calvin cycle, further integrating the light-dependent and light-independent pathways. **Review** [Figure 10.13](#)

► 10.4 Plants Have Adapted Photosynthesis to Environmental Conditions

- Rubisco can catalyze a reaction between O_2 and RuBP in addition to the reaction between CO_2 and RuBP. At high temperatures and low CO_2 concentrations, the oxygenase function of rubisco is favored over its carboxylase function.
- The oxygenase reaction catalyzed by rubisco significantly reduces the efficiency of photosynthesis. The subsequent reactions of [photorespiration](#) recover some of the fixed carbon that otherwise would be lost. **Review** [Figure 10.14](#)

photorespiration Light-driven uptake of oxygen and release of carbon dioxide, the carbon being derived from the early reactions of photosynthesis.

- In **C₄** plants, CO_2 reacts with [phosphoenolpyruvate \(PEP\)](#) to form a four-carbon intermediate in mesophyll cells. The four-carbon product releases its CO_2 to rubisco in the [bundle sheath cells](#) in the interior of the leaf. **Review** [Figures 10.15](#), [10.16](#), [Activity 10.2](#)

phosphoenolpyruvate (PEP) Phosphorylated salt of a three-carbon acid, formula $\text{OPO}_3\text{H}_2\text{—CO—CO—COOH}$ that is an intermediate in metabolic pathways such as glycolysis.

bundle sheath cell Part of a tissue that surrounds the veins of plants.

- [Crassulacean acid metabolism \(CAM\)](#) plants operate much like **C₄** plants, but their initial CO_2 fixation by PEP carboxylase is temporally separated from the Calvin cycle, rather than spatially separated as in **C₄** plants.

crassulacean acid metabolism (CAM) A metabolic pathway enabling the plants that possess it to store carbon dioxide at night and then perform photosynthesis during the day with stomata closed.

► 10.5 Photosynthesis Is an Integral Part of Plant Metabolism

- Photosynthesis and cellular respiration are linked through the Calvin cycle, the citric acid

cycle, and glycolysis. **Review** [Figure 10.17](#)

- To survive, a plant must photosynthesize more than it respires.
- Photosynthesis uses only a small portion of the energy of sunlight. **Review** [Figure 10.18](#)

Review

0.3 Light affects photosynthetic carbon fixation.

Original Paper: Loach, K. 1967. Shade tolerance in tree seedlings: I. Leaf photosynthesis and respiration in plants raised under artificial shade. *New Phytologist* 66: 607–621.

Some plants are shade-tolerant, and others thrive in sunlight. This phenomenon raises questions, because all plants use the same basic photosynthetic process. What makes shade-tolerant plants different from shade-intolerant plants, allowing them to grow well in low light? Can plants adapt to cope with unfavorable lighting conditions?

Researchers explored these questions by studying seedlings of two tree species—one shade-tolerant (beech) and one shade-intolerant (quaking aspen). The researchers planted newly germinated seedlings of both species under frames and covered the frames with shade cloth, limiting the amount of sunlight getting through to either 3% or 44% of normal daylight.

After 5 weeks the researchers moved one leaf, still attached to each plant, out of the frame so it could be studied briefly. They exposed each leaf to varying light intensities for several minutes, while measuring the rate of photosynthesis in its cells. Then leaves were removed and analyzed for chlorophyll content by mass, density of chlorophyll in the leaf, and leaf surface area. The last measurement was expressed as surface area per gram of leaf tissue so that the two species, which have different leaf sizes, could be compared. The results are shown in the graphs at right and in the table below. Note on the x-axis that normal daylight is about 4.5 thousand foot-candles.

Species	Shade tolerance	Cultivation light intensity (% sunlight)	Total chlorophyll		Specific leaf surface area (dm ² /g)
			(mg/g dry weight leaf)	(mg/dm ² leaf)	
Beech	Very tolerant	44	3.26	1.53	2.13
		3	7.02	2.82	2.49
Quaking aspen	Very intolerant	44	6.34	3.62	1.57
		3	8.23	4.38	1.88

Questions

1. In the graphs showing photosynthesis rates as a function of light intensity, every curve has the same basic shape. Why does the photosynthesis rate represented by each curve increase as the leaf is exposed to higher light intensities?
2. Look at the y-axis values on the two graphs, and compare the maximum photosynthesis rates for the two tree species. What does this suggest about a difference between shade-tolerant plants and shade-intolerant plants?
3. Analyze the chlorophyll data in the table. In general, how and why do plants adjust their levels of chlorophyll when raised in different light conditions?
4. Analyze the leaf surface area data in the table. How do shade-tolerant plants compare with shade-intolerant plants in specific leaf surface area, and why does this support adaptation to shade?
5. Predict which type of plant (shade-tolerant or shade-intolerant) will have the greatest fluctuation in photosynthesis rates over time in response to changes that occur in a single day as the skies go from overcast to clear and back to overcast.

* **connect the concepts** [Chapter 57](#) describes the sequence of energy flow through a community, including food chains and food webs.

▶ 11.1 All Cells Derive from Other Cells

- Cell division is necessary for the reproduction, growth, and repair of organisms.
- Cell division must be initiated by a **reproductive signal**. Before a cell can divide, the genetic material (DNA) must be **replicated** and **segregated** to separate portions of the cell. **Cytokinesis** then divides the cytoplasm into two cells.

reproductive signal In cell biology, the internal or external signal that causes a cell to initiate its mitotic or meiotic cell division cycle.

cytokinesis (sy' toe kine ee' sis) [Gk. *kytos*: container + *kinein*: to move] The division of the cytoplasm of a dividing cell. (Contrast with mitosis.)

- In prokaryotes, most cellular DNA is a single molecule, a **chromosome**. Prokaryotes reproduce by **binary fission**. **Review Figure 11.2**

chromosome (krome' o sowm) [Gk. *kroma*: color + *soma*: body] In bacteria and viruses, the DNA molecule that contains most or all of the genetic information of the cell or virus. In eukaryotes, a structure composed of DNA and proteins that bears part of the genetic information of the cell.

binary fission Reproduction of a prokaryote by division of a cell into two comparable progeny cells.

- In eukaryotes, cells divide by either mitosis or meiosis. In contrast to prokaryotes, eukaryotic cells have a distinct nucleus whose chromosomes are replicated prior to separating into two daughter cells.

▶ 11.2 The Eukaryotic Cell Division Cycle Is Regulated

- The eukaryotic cell cycle has two main phases: interphase, during which cells are not dividing and the DNA is replicating, and mitosis or M phase, when the cells are dividing.
- During most of the eukaryotic cell cycle, the cell is in interphase, which is divided into three subphases: S, G₁, and G₂. DNA is replicated during **S phase**. Mitosis (M phase) and cytokinesis follow. **Review Focus: Key Figure 11.3**

S phase In the cell cycle, the stage of interphase during which DNA is replicated. (Contrast with G₁ phase, G₂ phase.)

- Cyclin–Cdk complexes regulate the passage of cells through checkpoints in the cell cycle. Retinoblastoma protein (RB) inhibits the cell cycle at the **restriction (R) point**. One cyclin–Cdk functions by inactivating RB and allows the cell cycle to progress. **!!Review Figures 11.4, 11.5**
- External controls such as **growth factors** can stimulate the cell to begin a division cycle.

growth factor A chemical signal that stimulates cells to divide.

▶ 11.3 Eukaryotic Cells Divide by Mitosis

!![See Animation 11.1](#)

- In mitosis, a single nucleus gives rise to two nuclei that are genetically identical to each other and to the parent nucleus.
- DNA is wrapped around proteins called histones, forming beadlike units called [nucleosomes](#). A eukaryotic chromosome contains strings of nucleosomes bound to proteins in a complex called [chromatin](#). [Review Figure 11.8](#)

nucleosome A portion of a eukaryotic chromosome, consisting of part of the DNA molecule wrapped around a group of histone molecules, and held together by another type of histone molecule. The chromosome is made up of many nucleosomes.

chromatin The nucleic acid–protein complex that makes up eukaryotic chromosomes.

- At mitosis, the replicated chromosomes ([sister chromatids](#)) are held together at the [centromere](#). Each chromatid consists of one double-stranded DNA molecule. During mitosis sister chromatids, attached by cohesin, line up at the equatorial plate and attach to the [spindle apparatus](#). The chromatids separate (becoming [daughter chromosomes](#)) and migrate to opposite ends of the cell. !![Review Figures 11.9, 11.10, Activities 11.1, 11.2](#)

sister chromatid Each of a pair of newly replicated chromatids.

centromere (sen' tro meer) [Gk. *centron*: center + *meros*: part] The region where sister chromatids join.

spindle apparatus [O.E. *spindle*: a short stick with tapered ends] Array of microtubules emanating from both poles of a dividing cell during mitosis and playing a role in the movement of chromosomes at nuclear division.

daughter chromosomes During mitosis, the separated chromatids from the beginning of anaphase onward.

- Mitosis can be divided into several phases called prophase, prometaphase, metaphase, anaphase, and telophase.
- Nuclear division is usually followed by cytokinesis. Animal cell cytoplasm divides via a contractile ring made up of actin microfilaments and myosin. In plant cells, cytokinesis is accomplished by vesicles that fuse to form a cell plate. [Review Figure 11.12](#)

▶ 11.4 Cell Division Plays Important Roles in the Sexual Life Cycle

- **Asexual reproduction** produces [clones](#), new organisms that are genetically identical to the parent. Any genetic variation is the result of changes in genes.

clone

[Gk. *klon*: twig, shoot] (1) Genetically identical cells or organisms produced from a common ancestor by asexual means. (2) To produce many identical copies of a DNA sequence by its introduction into, and subsequent asexual reproduction of, a cell or organism.

- In [sexual reproduction](#), two [haploid](#) gametes—one from each parent—unite in [fertilization](#) to form a genetically unique, **diploid zygote**. Sexual life cycles can be haplontic, diplontic, or involve alternation of generations. !![Review Figure 11.14](#),

Activity 11.3

sexual reproduction Reproduction involving the union of gametes.

haploid (hap' loid) [Gk. *haploeides*: single] Having a chromosome complement consisting of just one copy of each chromosome; designated $1n$ or n . (Contrast with diploid.)

fertilization Union of gametes. Also known as syngamy.

- In non-haplontic sexually producing organisms, certain cells in the adult undergo meiosis to produce gametes, each of which contains one copy of each of the homologous chromosome pairs of the organism.

▶ 11.5 Meiosis Leads to the Formation of Gametes

!!See [Animation 11.2](#), [Activity 11.4](#)

- Meiosis consists of two nuclear divisions, [meiosis I](#) and [meiosis II](#), that reduce the chromosome number from diploid to haploid. Meiosis ensures that each haploid cell contains one member of each chromosome pair, and results in four genetically diverse haploid cells, usually gametes. !!Review [Figure 11.15](#), [Activity 11.5](#)

meiosis I See meiosis.

meiosis II See meiosis.

- In meiosis I, entire chromosomes, each with two chromatids, migrate to the poles. In meiosis II, the sister chromatids separate.
- During prophase I, homologous chromosomes undergo [synapsis](#) to form pairs in a [tetrad](#). Chromatids can form junctions called [chiasmata](#), and genetic material may be exchanged between the two homologs by [crossing over](#). Review [Figures 11.16](#), [11.17](#)

synapsis (sin ap' sis) The highly specific parallel alignment (pairing) of homologous chromosomes during the first division of meiosis.

tetrad [Gk. *tettares*: four] During prophase I of meiosis, the association of a pair of homologous chromosomes or four chromatids.

chiasma (kie az' muh) (plural: chiasmata) [Gk. cross] An X-shaped connection between paired homologous chromosomes in prophase I of meiosis. A chiasma is the visible manifestation of crossing over between homologous chromosomes.

crossing over The mechanism by which linked genes undergo recombination. In general, the term refers to the reciprocal exchange of corresponding segments between two homologous chromatids.

- Both crossing over during prophase I and [independent assortment](#) of the homologs as they separate during anaphase I ensure that the gametes are genetically diverse.

independent assortment During meiosis, the random separation of genes carried on nonhomologous chromosomes into gametes so that inheritance of these genes is random. This principle was articulated by Mendel as his second law.

- In **nondisjunction**, two members of a homologous pair of chromosomes go to the same pole during meiosis I, or two chromatids go to the same pole during meiosis II or mitosis.

This leads to one gamete having an extra chromosome and another lacking that chromosome. **Review Figure 11.19**

- The union between a gamete with an abnormal chromosome number and a normal haploid gamete results in **aneuploidy**. Such genetic abnormalities can be harmful or lethal to the organism.

aneuploidy (an' you ploy dee) A condition in which one or more chromosomes or pieces of chromosomes are either lacking or present in excess.

- The numbers, shapes, and sizes of the metaphase chromosomes constitute the **karyotype** of an organism.

karyotype The number, forms, and types of chromosomes in a cell.

- **Polyploids** have more than two sets of haploid chromosomes. Sometimes these sets come from different species.

polyploid (pol' lee ploid) Possessing more than two entire sets of chromosomes.

▶ 11.6 Cell Death Is Important in Living Organisms

- A cell may die by **necrosis**, or it may self-destruct by **apoptosis**, a genetically programmed series of events that includes the fragmentation of the cell's nuclear DNA.

necrosis (nec roh' sis) [Gk. *nekros*: death] Premature cell death caused by external agents such as toxins.

apoptosis (ap uh toh' sis) A series of genetically programmed events leading to cell death.

- Apoptosis is regulated by external and internal signals. These signals result in activation of a class of enzymes called **caspases** that hydrolyze proteins in the cell. **Review Figure 11.21**

caspase One of a group of proteases that catalyze cleavage of target proteins and are active in apoptosis.

▶ 11.7 Unregulated Cell Division Can Lead to Cancer

- Cancer cells divide more rapidly than normal cells and can be **metastatic**, spreading to distant organs in the body.
- Cancer can result from changes in either of two types of proteins that regulate the cell cycle. **Oncogene** proteins stimulate cell division and are activated in cancer. **Tumor suppressor** proteins normally inhibit the cell cycle, but in cancer they are inactive. **Review Figure 11.23**

oncogene [Gk. *onkos*: mass, tumor + *genes*: born] A gene that codes for a protein product that stimulates cell proliferation. Mutations in oncogenes that result in excessive cell proliferation can give rise to cancer.

tumor suppressor A gene that codes for a protein product that inhibits cell proliferation; inactive in cancer cells. (Contrast with oncogene.)

- Multiple genetic events are necessary to form a malignant cancer cell. **Review Figure 11.24**
- Cancer treatment often targets the cell cycle in tumor cells. **Review [Figure 11.25](#)**

Review

1.7 Cell cycle abnormalities play an important role in the development of cancer.

1.7 Cancer therapies are targeted to events in the cell cycle.

The healing properties of plants have been known for thousands of years. When laboratory techniques became sophisticated enough to begin isolating such compounds from living things, scientists turned to plants as potential sources of anticancer drugs. Since then, countless candidates—from tiny flowering plants to giant pine trees—have been screened for anticancer properties.

Researchers use water or other solvents to make extracts from plants. They test the extracts first on cancer cells and then on animal models. Those extracts that have anticancer activities are studied to see how they work.

One way in which cells become cancerous is that they lose control of the cell cycle. There are four checkpoints involved in this control, each with cyclin and cyclin-dependent kinase (Cdk).

The table below summarizes results from tests in which plant extracts were tested for their ability to inhibit cyclin-Cdk enzyme activity. Note that the naming of cyclins (A, B, etc.) and Cdks (1, 2, etc.) is arbitrary and does not indicate where they act in the cell cycle. Enzyme activity is expressed as +++ for full activity and as 0 for no activity.

Plant extract	Cyclin D-Cdk4 activity	Cyclin E-Cdk2 activity	Cyclin A-Cdk2 activity	Cyclin B-Cdk1 activity
1	+++	+++	0	+++
2	+++	+++	+++	0
3	0	+++	+++	+++

Questions

1. Scientists can coax a group of cells to grow in synchrony so that all cells pass through the same cell cycle phases at the same time. What would you expect to observe if, in separate experiments, you added each of the four plant extracts to cancer cells in early G1?
2. Tumors have billions of cells. Very few tumors respond to a single drug that affects the cell cycle. Combination chemotherapy, targeting several checkpoints, is often used. Can you suggest a reason for this? (Hint: Not all cancer cells are the same.)
3. What would a researcher have to do to develop drugs from the plant extracts that could be administered to human cancer patients for halting tumor growth?
4. In some cancer cells, hyperactivation of cyclin–Cdk complexes results from greater-than-normal quantities of either cyclin or Cdk proteins. Suppose the following data were collected from various cells. Based on these data, which plant extract would be most useful for treating the tumor from which the cancer cells were taken?

Ratio of protein expressed in cancer cells versus noncancer cells	
Cyclin A	0.98
Cyclin B	0.99
Cyclin D	1.02
Cyclin E	1.01
Cdk1	4.25
Cdk2	0.95
Cdk4	0.98
Cdk6	1.04

5. Each Cdk shown above is regulated by another group of proteins. For each Cdk, there is a kinase that inhibits Cdk from binding to cyclin and a phosphatase that activates Cdk binding to cyclin. The diagram below shows kinase inactivation using a plus symbol and phosphatase activation using a minus symbol. Suppose researchers found a plant extract that halted kinase activity and another that halted phosphatase activity. Would the researchers be interested in one or both extracts as potential sources of an anti-cancer drug? Explain.

The Cell Cycle and Cell Division

Henrietta Lacks's tumor cells have far outlived her sad demise from cancer. They reproduce rapidly on the surface of a solid medium and have been grown in labs since her death in 1951.

Immortal Cells

On January 29, 1951, 30-year-old Henrietta Lacks visited the nearby Johns Hopkins Hospital in Baltimore, Maryland, because she had been bleeding abnormally after the birth of her last child. The physician found the reason for the bleeding: a tumor the size of a quarter on her cervix. A piece of the tumor was sent to a pathologist in a clinical laboratory, who reported that the tumor was malignant.

A week later Ms. Lacks returned to the hospital, where physicians treated her tumor with radiation to try to kill it. But before the treatment began, they took a small sample of cells and sent them without her permission—a practice common then but not ethical today—to the research lab of George and Margaret Gey, two scientists at the hospital who had been trying for 20 years to coax human cells to live and multiply outside the body. If they could do so, they thought, they might find a cure for cancer. The Geys hit pay dirt with Lacks's cells; they grew and reproduced more vigorously than any cells they had ever seen and were given the name “HeLa cells.” Unfortunately, they also grew fast in Lacks's body, and in a few months they had spread to almost all of her organs. Lacks died on October 4, 1951.

Because of their robust ability to reproduce, HeLa cells quickly became a staple of cell biology research. In controlled settings they could be infected with viruses, and they were instrumental in developing the supply of polioviruses that led to the first vaccine against that dread disease. HeLa cells have been used for important basic and applied research ever since, especially on the ways that human cells reproduce by cell division. Although Lacks had never been outside Virginia and Maryland, her cells have traveled all over the world and even into space on the space shuttle. Over the past 60 years, tens of thousands of research articles have been published using information obtained from Lacks's cells. You'll study one of them in this chapter.

Understanding the cell division cycle and its control is clearly an important subject for understanding cancer. But cell division is not just important in medicine. It underlies the growth, development, and reproduction of all organisms.

What controls the reproduction of cancer cells?

11.1 All Cells Derive from Other Cells

The life cycle of an organism, from birth to death, is intimately linked to cell division. Cell division plays important roles in the development of an organism from a single cell, in the growth and repair of tissues in multicellular organisms, and in the reproduction of all organisms ([Figure 11.1](#)). Cell division in both prokaryotes and eukaryotes entails the following four events:

(A) Reproduction

These eukaryotic yeast cells divide by budding.

(B) Growth

Cell division contributes to the growth of this root tissue.

(C) Regeneration

Figure 11.1 Important Consequences of Cell Division Cell division is the basis for (A) reproduction, (B) growth, and (C) repair and regeneration of tissues.

- . A **reproductive signal**. An intracellular or extracellular signal initiates cell division.
- . **Replication** of DNA. The cell's genetic material must be duplicated so that each of the two new cells will have a complete, identical set of genes.
- . **Segregation** of replicated DNA. The replicated DNA must be equally distributed to each of the two new cells.
- . **Cytokinesis**. Enzymes and organelles for the new cells must be synthesized, and new material must be added to the cell membrane (and the cell wall, in organisms that have one), in order to separate the two new cells.

reproductive signal In cell biology, the internal or external signal that causes a cell to initiate its mitotic or meiotic cell division cycle.

replication The duplication of genetic material.

segregation In genetics, the separation of alleles, or of homologous chromosomes, from each other during meiosis so that each of the haploid daughter nuclei produced contains one or the other member of the pair found in the diploid parent cell, but never both. This principle was articulated by Mendel as his first law.

cytokinesis (sy' toe kine ee' sis) [Gk. *kytos*: container + *kinein*: to move] The division of the cytoplasm of a dividing cell. (Contrast with mitosis.)

As you will see, these four events happen differently in prokaryotes and eukaryotes.

All cell division processes involve four main events: initiation, DNA replication, DNA segregation, and cytokinesis.

Cell division in prokaryotes is rapid, occurs in response to environmental signals, and results in new individual cells, which are often the entire organism.

Cell division in eukaryotes is complex, occurs in response to internal signals, and may reproduce the entire organism for single-celled eukaryotes, or result in more cells within a multicellular organism.

Prokaryotes divide by binary fission

In prokaryotes, cell division results in the reproduction of the entire single-celled organism. The cell grows in size, replicates its DNA, and then separates the cytoplasm and DNA into two new cells in a process called [binary fission](#).

binary fission Reproduction of a prokaryote by division of a cell into two comparable progeny cells.
--

REPRODUCTIVE SIGNALS

External factors such as environmental conditions and nutrient concentrations are common signals for the initiation of cell division in prokaryotes. For example, the bacterium *Bacillus subtilis* divides every 120 minutes if abundant sources of carbohydrate and mineral nutrients are available. When nutrient levels are low, it slows down its growth and eventually stops dividing. When conditions improve, growth and division resume. The bacterium *Escherichia coli*, which is widely used in genetic studies, divides every 20 minutes if abundant sources of carbohydrates and mineral nutrients are available.

REPLICATION OF DNA

As you saw in [Key Concept 5.3](#), a [chromosome](#) consists of a long, thin DNA molecule with proteins attached to it. When a cell divides, all of its chromosomes, which contain the genetic information for the organism, must be replicated, and one copy of each chromosome must find its way into each of the two new cells.

chromosome (krome' o sowm) [Gk. <i>kroma</i>: color + <i>soma</i>: body] In bacteria and viruses, the DNA molecule that contains most or all of the genetic information of the cell or virus. In eukaryotes, a structure composed of DNA and proteins that bears part of the genetic information of the cell.

Most prokaryotes have just one main chromosome. If the *E. coli* chromosome were spread out into a full circle, the circle would be about 500 micrometers (µm) in diameter, more than 200 times larger than the cell! To fit into the cell, bacterial DNA must be compacted. The DNA folds in on itself, and positively charged (basic) proteins bound to the negatively charged (acidic) DNA contribute to this folding.

Two regions of the prokaryotic chromosome play functional roles in cell reproduction:

- . *ori*: the site where replication of the circular chromosome starts (the *origin* of replication)
- . *ter*: the site where replication ends (the *terminus* of replication)

Chromosome replication takes place as the DNA is threaded through a replication complex of

proteins near the center of the cell. Replication begins at the *ori* site and moves bidirectionally toward the *ter* site. While the DNA replicates, anabolic metabolism is active, resulting in cell growth. When replication is complete, the two daughter DNA molecules separate and segregate from one another at opposite ends of the cell. In rapidly dividing prokaryotes, DNA replication occupies the entire time between cell divisions.

SEGREGATION OF DNA MOLECULES

Replication begins near the center of the cell, and as it proceeds, the *ori* regions move toward opposite ends of the cell ([Figure 11.2A](#)). DNA sequences adjacent to the *ori* region bind proteins that are essential for this segregation. This is an energy-requiring process, since the binding proteins hydrolyze ATP.

(A) Binary fission in a bacterium

(B) Cytokinesis in a bacterium

Figure 11.2 Prokaryotic Cell Division

CYTOKINESIS

Immediately after chromosome replication is finished, cytokinesis begins. At first, the cell membrane pinches in to form a ring of fibers similar to a purse string. The major component of these fibers is a protein called FtsZ that is related to eukaryotic tubulin (which makes up microtubules; see [Figure 5.14](#)). As the membrane pinches in, new cell wall materials are deposited, which finally separate the two cells ([Figure 11.2B](#)).

Eukaryotic cells divide by mitosis followed by cytokinesis

As in prokaryotes, cell reproduction in eukaryotes entails reproductive signals, DNA replication, segregation, and cytokinesis. The details, however, are quite different:

Reproductive signal: Unlike prokaryotes, eukaryotic cells do not constantly divide whenever environmental conditions are adequate. In fact, most eukaryotic cells that are part of a multicellular organism and have become specialized seldom divide. In a eukaryotic organism, the signals for cell division are usually not related to the environment of a single cell, but to the function of the entire organism.

Replication: Whereas most prokaryotes have a single main chromosome, eukaryotes usually have many (humans have 46). Consequently the processes of replication and segregation are more intricate in eukaryotes than in prokaryotes. In eukaryotes, DNA replication is usually limited to part of the period between cell divisions.

Segregation: In eukaryotes, the newly replicated chromosomes are closely associated with each other (thus they are known as [sister chromatids](#)), and a mechanism called [mitosis](#) segregates them into two new nuclei.

Cytokinesis: Cytokinesis proceeds differently in plant cells (which have a cell wall) than in animal cells (which do not).

sister chromatid Each of a pair of newly replicated chromatids.

mitosis (my toe' sis) [Gk. *mitos*: thread] Nuclear division in eukaryotes leading to the formation of two daughter nuclei, each with a chromosome complement identical to that of the original nucleus.

The cells resulting from mitosis are identical to the parent cell in the amount and kind of DNA

they contain.

There is another mechanism for nuclear division called **meiosis**, which is involved in gamete formation. We will return to meiosis and describe differences with mitosis in [Key Concept 11.5](#).

meiosis (my oh' sis) [Gk. *meiosis*: diminution] Division of a diploid nucleus to produce four haploid daughter cells. The process consists of two successive nuclear divisions with only one cycle of chromosome replication. In meiosis I, homologous chromosomes separate but retain their chromatids. The second division meiosis II, is similar to mitosis, in which chromatids separate.

11.1 recap

Four events are required for cell division: a reproductive signal, replication of the genetic material (DNA), segregation of replicated DNA, and separation of the two daughter cells (cytokinesis). Prokaryotes often have just one chromosome, and cell division can be rapid. Eukaryotes usually have multiple chromosomes, and the process of cell division is more intricate, involving either mitosis or meiosis.

learning outcomes

You should be able to:

- Analyze and explain the steps found in all cell division processes and their sequence.
- Describe the cell division process in prokaryotes.
- Explain how the four events of cell division occur in eukaryotic cells.
- Compare and contrast cell division in prokaryotes and eukaryotes.

- [1.](#) What commonly limits the reproduction of a prokaryotic cell by binary fission?
- [2.](#) Why must DNA be replicated and segregated before the cell can divide?
- [3.](#) Why are DNA replication and cell division more complex in eukaryotes than in prokaryotes?

What determines whether a eukaryotic cell will divide? How does mitosis lead to identical cells? In the sections that follow, we will describe the details of mitosis.

11.2 The Eukaryotic Cell Division Cycle Is Regulated

As you will see throughout this book, different cells have different rates of cell division. Some cells, such as those in an early embryo, divide rapidly and continuously. Others, such as neurons in the brain, don't divide at all. This suggests that the signaling pathways for cells to divide are highly controlled.

focus your learning

Dividing eukaryotic cells undergo an orderly sequence of events that together make up the cell cycle.

Events of the eukaryotic cell cycle are internally regulated.

External factors stimulate eukaryotic cells in the G0 state to begin dividing.

In eukaryotes, the period from one cell division to the next is known as the [cell cycle](#). The cell cycle can be divided into mitosis/cytokinesis and interphase. During [interphase](#), the cell nucleus is visible and typical cell functions occur, including DNA replication. Interphase begins when cytokinesis is completed and ends when mitosis (M) begins (**Focus: Key Figure 11.3**). In this section we will describe the events of interphase, especially those that trigger mitosis.

cell cycle The stages through which a cell passes between one mitotic division and the next. Includes all stages of interphase and mitosis. (See mitosis.)

interphase In the cell cycle, the period between successive nuclear divisions during which the chromosomes are diffuse and the nuclear envelope is intact. During interphase the cell is most active in transcribing and translating genetic information.

focus: key figure

Figure 11.3 The Eukaryotic Cell Cycle The cell cycle consists of a mitotic (M) phase, during which mitosis and cytokinesis take place, and a long period of growth known as interphase. Interphase has three subphases (G1, S, and G2) in cells that divide.

Q: If the DNA content of a human skin cell at the beginning of mitosis is 12 picograms ($1 \text{ pg} = 10^{-12} \text{ g}$), what is the DNA content of a cell in G1?

The duration of the cell cycle varies considerably in different cell types. In the early embryo the cell cycle may be as short as 30 minutes, whereas rapidly dividing cells in an adult human typically complete the cycle in about 24 hours. In general, cells spend most of their time in interphase. So if we take a snapshot through the microscope of a cell population, only a few cells will be in mitosis or cytokinesis at any given moment. Interphase has three subphases called G1, S, and G2. In a cell cycle of 24 hours, these subphases would typically last for 11

hours (G1), 8 hours (S), and 4 hours (G2), with the remaining 1 hour spent in mitosis.

G1 phase. During [G1 phase](#), each chromosome is a single, unreplicated DNA molecule with associated proteins. Variations in the duration of G1 account for most of the variability in the length of the cell cycle in different cell types. Some rapidly dividing embryonic cells dispense with it entirely, whereas other cells may remain in G1 for weeks or even years.

The G1-to-S transition. At the [G1-to-S transition](#) the commitment is made to DNA replication and subsequent cell division.

S phase. DNA replication occurs during [S phase](#) (see [Key Concept 13.3](#) for a detailed description of DNA replication). Each chromosome is duplicated and thereafter consists of two sister chromatids (the products of DNA replication). The sister chromatids remain joined together until mitosis, when they segregate into two daughter cells.

G2 phase. During [G2 phase](#), the cell makes preparations for mitosis—for example, by synthesizing and assembling the structures that move the chromatids to opposite ends of the dividing cell.

G1 In the cell cycle, the gap between the end of mitosis and the onset of the S phase.

G1-to-S transition In the cell cycle, the point at which G1 ends and the S phase begins.

S phase In the cell cycle, the stage of interphase during which DNA is replicated. (Contrast with G1 phase, G2 phase.)

G2 In the cell cycle, the gap between the S (synthesis) phase and the onset of mitosis.

The initiation, termination, and operations of these phases are regulated by specific signals. Not all cells follow this “march through the phases.” Some cells in G1 enter an inactive resting phase of the cell cycle called [G0](#). These cells sometimes return to G1 and the rest of the cell cycle under certain environmental conditions, such as an extracellular signal. Otherwise, cells may stay in G0; examples in humans are cells of the heart (cardiac muscle) and brain (neurons).

G0 A resting phase in which a cell is not preparing for the cell division cycle.

Specific internal signals trigger events in the cell cycle

Cell fusion experiments were used to reveal the existence of internal signals that control the transitions between stages of the cell cycle. For example, an experiment involving the fusion of HeLa cells (the cells described in the opening story) at different phases of the cell cycle showed that a cell in S phase produces a substance that activates DNA replication (**Investigating Life: What Controls the Reproduction of Cancer Cells?**). Similar experiments pointed to the existence of signals controlling entry into M phase. Additional experiments showed that cell cycle progression signals are controlled by protein kinase activity.

 **What Controls the
Reproduction of Cancer Cells?**

experiment

Original Paper: Rao, P. N. and R. T. Johnson, 1970. Mammalian cell fusion: Studies on the regulation of DNA synthesis and mitosis. *Nature* 225: 159–164.

Nuclei of cells in G1 phase do not undergo DNA replication, but nuclei in S phase do. Rao and Johnson wondered whether substances present in cells in the S phase could be used to induce DNA replication in cells in the G1 phase.

HYPOTHESIS ▶ A cell in S phase contains an activator of DNA replication.

METHOD

RESULTS

CONCLUSION ▶ The S phase cell contains a substance that diffuses to the G1 nucleus and activates DNA replication.

work with the data

The fusion of cellular membranes is a natural process; it occurs during endocytosis and exocytosis, and in fertilization (the fusion of gametes). Membrane fusion also occurs when membrane-enclosed viruses infect their host cells. Occasionally these viruses also induce the fusion of adjacent host cells, creating a multinucleate cell. This observation led to the use of Sendai virus, a membrane-enclosed mouse respiratory virus, as a tool in the laboratory to fuse cells experimentally. Rao and Johnson used this strategy to study the regulation of the cell cycle.

In their experiment, Rao and Johnson used HeLa cells, which divide continuously (see the opening story of this chapter). First, they isolated cells in either G1 or S phase. Before fusion, the cells in S phase were exposed to a radioactively labeled component of DNA (thymidine). The radioactivity was incorporated into these cells' newly replicated DNA, labeling their nuclei. The S and G1 cells were then fused using Sendai virus (resulting in G1/S fusions) and again exposed to labeled thymidine. At various times after fusion, the scientists calculated the percent of previously unlabeled (G1) nuclei that had incorporated new label (i.e., had replicated their DNA) (Figure A). In a second series of experiments, S and G2 cells were fused in various combinations and then the numbers of cells in mitosis were counted and expressed as a percent of all cells in the population (Figure B).

Figure A

Figure B

QUESTIONS

1. According to Figure A, how long did it take for all the G1 nuclei in the G1/S cells to become labeled?
2. Examine the data for fused G1/G1 cells and unfused G1 cells in Figure A. Explain why these were appropriate controls for the experiment. When did these nuclei become labeled? Compare these times with each other and with that for the G1/S nuclei and discuss.
3. Examine the data in Figure B. Why did it take longer for the S phase cells to begin mitosis than the G2 cells?
4. According to Figure B, did fusion with G2 cells alter the timing of mitosis in the S cell nuclei? Explain what this means in terms of regulation of the cell cycle.

Progress through the cell cycle depends on the activities of **cyclin-dependent kinases**, or **Cdk's**. Recall from **Key Concept 7.2** that a protein kinase is an enzyme that catalyzes the transfer of a phosphate group from ATP to a target protein; this phosphate transfer is called phosphorylation.

cyclin-dependent kinase (Cdk) A protein kinase whose target proteins are involved in transitions in the cell cycle and which is active only when complexed with additional protein subunits, called cyclins.

Cdk See cyclin-dependent kinase.

Protein + ATP → Protein kinase protein-P + ADP(Changed shape and activity)

Protein + ATP $\xrightarrow{\text{Protein kinase}}$ protein-P + ADP
(Changed shape and activity)

By catalyzing the phosphorylation of certain target proteins, Cdk's play important roles at various points in the cell cycle. The discovery that Cdk's induce cell division is a beautiful example of how research on different organisms and different cell types can converge on a single idea. One group of scientists, led by James Maller at the University of Colorado, was studying immature frog eggs, trying to find out how they are stimulated to divide and eventually form mature eggs. They found that when they added a protein from maturing eggs to immature eggs cells, the latter were stimulated to divide. They named the protein, maturation promoting factor.

Meanwhile, Leland Hartwell at the University of Washington was studying the cell cycle in yeast (a single-celled eukaryote; see [Figure 11.1A](#)) and found a strain that was stalled at the G1–S boundary and determined that it lacked a Cdk. It turned out that this yeast Cdk and the sea urchin maturation promoting factor had similar properties, and further work confirmed that the sea urchin protein was indeed a Cdk!

Similar Cdk's were soon found to control the G1-to-S transition in many other organisms, including humans. This control point in the cell cycle is now called the **restriction (R) point**. Other Cdk's were found to control other parts of the cell cycle.

Cdk's are not enzymatically active as protein kinases unless they are bound to another class of protein, the activator called cyclin. This binding—an example of ***allosteric regulation**—activates the Cdk by altering its shape and exposing its active site to substrates ([Figure 11.4](#)). The cyclin–Cdk that controls passage from G1 to S phase is not the only such complex involved in regulating the eukaryotic cell cycle. There are different cyclin–Cdk complexes, composed of various cyclins and Cdk's that act at different stages of the cycle ([Figure 11.5](#)). The details of how these complexes form and function vary among eukaryotic organisms, but we will focus here on the complexes found in mammalian cells. As an example, let's take a closer look at the cyclin–Cdk complex that controls the G1-to-S transition.

Figure 11.4 Cyclin Binding Activates Cdk Binding of a cyclin changes the three-dimensional structure of an inactive Cdk, making it an active protein kinase. Each cyclin–Cdk complex phosphorylates a specific target protein in the cell cycle.

Figure 11.5 Cyclin-Dependent Kinases Regulate Progress through the Cell Cycle
By acting at checkpoints (red lines), different cyclin-Cdk complexes regulate the orderly sequence of events in the cell cycle.

Cyclin-Cdk catalyzes the phosphorylation of a protein called retinoblastoma protein (RB, named because of its role in cancer; see [Key Concept 11.7](#)). In many cells, RB or a protein like it acts as an inhibitor of the cell cycle at the R point. To begin S phase, a cell must get by the RB block. Here is where cyclin-Cdk comes in: it catalyzes the phosphorylation at multiple sites on the RB molecule. This causes a change in the three-dimensional structure of RB, thereby inactivating it. With RB out of the way, the cell cycle can proceed. To summarize:

RB → Cyclin-CdkRB-P (Active – blocks cell cycle) (Inactive – allows cell cycle)

RB ————— Cyclin-Cdk —————→ RB-P

(Active – blocks cell cycle) (Inactive – allows cell cycle)

Progress through the cell cycle is regulated by the activities of Cdk's, and so regulating *them* is a key to regulating cell division. An effective way to regulate Cdk's is to regulate the presence or absence of cyclins ([Figure 11.6](#)). Simply put, if a cyclin is not present, its partner Cdk is not active. As their name suggests, cyclins are present cyclically: they are made only at certain times in the cell cycle.

Figure 11.6 Cyclins Are Transient in the Cell Cycle Cyclins are made at a particular time and then break down. In this case, the cyclin is present during G1 and activates a Cdk at that time.

The different cyclin–Cdk’s act at [cell cycle checkpoints](#), signaling pathways that regulate the cell cycle’s progress. For example, if a cell’s DNA is substantially damaged by radiation or toxic chemicals, the cell may be prevented from successfully completing a cell cycle. During interphase, there are three checkpoints, with a fourth during mitosis (see [Figure 11.5](#); [Table 11.1](#)). The table lists the triggers that will cause the cell cycle to pause at each point.

cell cycle checkpoints Points of transition between different phases of the cell cycle, which are regulated by cyclins and cyclin-dependent kinases (Cdk’s).

table 11.1 Cell Cycle Checkpoints

Cell cycle phase	Checkpoint trigger
G1	DNA damage
S	Incomplete replication or DNA damage
G2	DNA damage
M	Chromosome unattached to spindle

As an example, let's consider the G1 checkpoint (R). If DNA is damaged by radiation during G1, a signaling pathway results in the production of a protein called p21. (The *p* stands for "protein" and the 21 stands for its molecular weight—about 21,000.) The p21 protein binds to the G1–S cdk, preventing cyclin binding. This keeps the cdk in its inactive state and the cell cycle pauses while repairs are made to the DNA (you will learn more about DNA repair in [Key Concept 13.4](#)). When the DNA damage pathway is no longer operating, p21 breaks down, allowing the cyclin–Cdk's to function, and the cell cycle proceeds. If DNA damage is severe and it cannot be repaired, the cell will undergo programmed cell death (apoptosis, which we will discuss later in this chapter). Such controls prevent defective cells from proliferating and potentially harming an organism.

Growth factors can stimulate cells to divide

Cyclin–Cdk's provide cells with internal controls of their progress through the cell cycle. But the cell cycle is also influenced by external signals. Not all cells in an organism go through the cell cycle on a regular basis. Some cells either no longer go through the cell cycle and enter G0, or go through it slowly and divide infrequently. If such cells are to divide, they must be stimulated by external chemical signals called [growth factors](#). Here are a few examples:

growth factor A chemical signal that stimulates cells to divide.

If you cut yourself and bleed, specialized cell fragments called platelets gather at the wound to initiate blood clotting. The platelets produce and release a protein called platelet-derived growth factor which diffuses to the adjacent cells in the skin and stimulates them to divide and heal the wound.

Red and white blood cells have limited lifetimes and must be replaced through the division of immature, unspecialized blood cell precursors in the bone marrow. Two types of growth factors, interleukins and erythropoietin, stimulate the division and specialization, respectively, of precursor cells of white blood cells and red blood cells.

Growth factors bind to specific receptors on target cells and activate signal transduction pathways (see [Chapter 7](#)) that end with cyclin synthesis, thereby activating Cdk's and the cell cycle.

11.2 recap

The eukaryotic cell cycle is under both external and internal control. Cdk's control the eukaryotic cell cycle, and their activities are regulated by binding of cyclins. External signals such as growth factors can initiate the cell cycle.

learning outcomes

You should be able to:

- Identify each phase of the cell cycle using diagrams or descriptions.
- Explain how the progress of a eukaryotic cell through the cell cycle is controlled.
- Describe the ways in which progress through the cell cycle is modulated.
- Predict the effects of external factors on the eukaryotic cell cycle.

1. Draw a cell cycle diagram and describe the three subphases of interphase.
2. How do cyclin–Cdk's control the progress of the cell cycle?
3. What are growth factors, and how do they act to control the cell cycle?
4. The protein p16 acts on the cell cycle in a fashion similar to that of p21. Recently it was found that there is more p16 protein in the cells of older people than in younger people. What are the implications of this for aging?

Once the cell cycle is initiated and interphase completed, the cell enters mitosis, where the replicated DNA is segregated into two daughter cells.

*** connect the concepts** As discussed in [Key Concept 8.5](#), allosteric regulation occurs when another molecule induces a change in the three-dimensional structure of an enzyme. This changes the ability of the enzyme to bind its substrate, and so changes the rate of the reaction catalyzed by the enzyme.

11.3 Eukaryotic Cells Divide by Mitosis

DNA is a very long polymer, up to several μm long. At every stage of the cell cycle, these threads must be packaged into compact structures. A eukaryotic chromosome consists of one or two linear, double-stranded DNA molecules bound with many proteins (the complex of DNA and proteins is referred to as **chromatin**). Before S phase, each chromosome contains only one double-stranded DNA molecule. After it replicates during S phase, however, there are two double-stranded DNA molecules: the sister chromatids (**Figure 11.7**). Throughout G2 the sister chromatids are held together along most of their length by a protein complex called cohesin. At mitosis most of the cohesin is removed, except in a region called the **centromere**, where the chromatids remain held together. At the end of G2 and the beginning of mitosis, a second group of proteins called condensins coats the DNA molecules and makes them more compact.

chromatin The nucleic acid–protein complex that makes up eukaryotic chromosomes.

centromere (sen' tro meer) [Gk. *centron*: center + *meros*: part] The region where sister chromatids join.

Figure 11.7 Chromosomes, Chromatids, and Chromatin DNA in the interphase nucleus is diffuse and becomes compacted as mitosis begins.

focus your learning

Mitosis ensures that each daughter cell receives one copy of the parent cell's DNA.

Mitosis involves ordered events within the dividing cell nucleus.

Cytokinesis is the process by which a cell's cytoplasm divides. It occurs once mitosis is complete.

If all of the DNA in a typical human cell were put end to end, it would be nearly 2 meters long. Yet the nucleus is only 5 μm (0.000005 meters) in diameter and therefore DNA must be extensively packaged in a highly organized way ([Figure 11.8](#)). This packing is achieved largely by proteins called histones (*histos*, “web” or “loom”), which are positively charged at cellular pH because of their high content of the basic amino acids lysine and arginine. The charged R groups on these amino acids bind to the negatively charged phosphate groups on DNA by ionic attractions. These DNA–histone interactions, as well as histone–histone interactions, result in the formation of beadlike units called [nucleosomes](#) (see [Figure 11.8](#)).

Figure 11.8 DNA Is Packed into a Mitotic Chromosome The nucleosome, formed by DNA and histones, is the essential building block in this highly compacted structure.

nucleosome A portion of a eukaryotic chromosome, consisting of part of the DNA molecule wrapped around a group of histone molecules, and held together by another type of histone molecule. The chromosome is made up of many nucleosomes.

During interphase, the chromatin that makes up each chromosome consists of single DNA molecules running around vast numbers of nucleosomes that resemble beads on a string. During this phase of the cell cycle, the DNA is accessible to proteins involved in replication and transcription. Once a mitotic chromosome is formed, its compact nature makes it inaccessible to replication and transcription factors, and so these processes cannot occur. Further coiling of the chromatin continues up to the time at which the chromatids begin to move apart.

In mitosis, a single nucleus gives rise to two nuclei that are genetically identical to each other and to the parent nucleus. Mitosis (the M phase of the cell cycle) ensures the accurate segregation of the eukaryotic cell's multiple chromosomes into the daughter nuclei. While

mitosis is a continuous process in which each event flows smoothly into the next, it is convenient to subdivide it into a series of stages: prophase, prometaphase, metaphase, anaphase, and telophase ([Figure 11.9](#), [Table 11.2](#)).

Figure 11.9 The Phases of Mitosis in an Animal Cell Mitosis results in two new genetically identical nuclei, each one destined for one of the two daughter cells produced when a cell divides. In the micrographs, the green dye stains microtubules (and thus the spindle); the red dye stains the chromosomes. The chromosomes in the diagrams are stylized to emphasize the fates of the individual chromatids.

table 11.2 Summary of Cell Cycle Events

Phase	Events
Interphase:	
G1	Growth; restriction point at end
S	DNA replication
G2	Spindle synthesis begins; preparation for mitosis
Mitosis:	
Prophase	Condensation of chromosomes; spindle assembly
Prometaphase	Nuclear envelope breakdown; chromosome attachment to spindle
Metaphase	Alignment of chromosomes at equatorial plate
Anaphase	Separation of chromatids; migration to poles
Telophase	Chromosomes decondense; nuclear envelope re-forms
Cytokinesis	Cell separation; cell membrane and/or wall formation

Let's take a closer look at two cellular structures that contribute to the orderly segregation of the chromosomes during mitosis—the centrosomes and the spindle.

Animation 11.1 **Mitosis** www.Life11e.com/a11.1

The centrosomes determine the plane of cell division

The **spindle apparatus** (also called the mitotic spindle or simply the spindle) is a dynamic microtubule structure that moves sister chromatids apart during mitosis. Before the spindle can form, its orientation is determined by the **centrosome** (“central body”), an organelle in the cytoplasm near the nucleus. In many organisms the centrosome consists of a pair of **centrioles**, each one a hollow tube formed by nine ***microtubule** triplets. During S phase the centrosome doubles, and at the beginning of prophase the two centrosomes separate from one another, moving to opposite ends of the nuclear envelope. These identify the “poles” toward which chromosomes move during anaphase. The cells of plants and fungi lack centrosomes, but distinct microtubule organizing centers at each end of the cell play the same role.

spindle apparatus [O.E. *spindle*: a short stick with tapered ends] Array of microtubules emanating from both poles of a dividing cell during mitosis and playing a role in the movement of chromosomes at nuclear division.

centrosome (sen' tro soam) The major microtubule organizing center of an animal cell.

centriole (sen' tree ole) A paired organelle that helps organize the microtubules in animal and protist cells during nuclear division.

The positions of the centrosomes determine the plane at which the animal cell will divide; therefore they determine the spatial relationship between the two new cells. This relationship may be of little consequence to single free-living cells such as yeasts, but it is important for cells in a multicellular organism. For example, during development from a fertilized egg to an embryo, the daughter cells from some divisions must be positioned correctly to receive signals to form new tissues.

The spindle begins to form during prophase

During interphase, only the nuclear envelope, the nucleoli (see [Key Concept 5.3](#)), and a barely discernible tangle of chromatin are visible under the light microscope. The appearance of the nucleus changes as the cell enters prophase. At this stage, most of the cohesin that has held the two products of DNA replication together since S phase is removed, so the individual chromatids become visible. They are still held together by a small amount of cohesin at the centromere. Late in prophase, specialized structures called [kinetochores](#) develop in the centromere region, one on each chromatid. These structures will be important for chromosome movement.

kinetochore (kuh net' oh core) Specialized structure on a centromere to which microtubules attach.

Each of the two centrosomes, now on opposite sides of the nucleus, serves as a mitotic center, or pole, toward which the chromosomes will move ([Figure 11.10A](#)). During prophase and prometaphase, microtubules form between the poles and the chromosomes to make up the spindle. The spindle serves as a structure to which the chromosomes attach and as a framework keeping the two poles apart. Each half of the spindle develops as tubulin dimers aggregate from around the centrioles and form long fibers that extend into the middle region of the cell. The microtubules are initially unstable, constantly forming and falling apart, until they contact kinetochores or microtubules from the other half-spindle and become more stable.

Figure 11.10 The Mitotic Spindle Consists of Microtubules (A) The spindle apparatus in an animal cell at metaphase. In plant cells, centrioles are not present. **(B)** An electron micrograph of metaphase, emphasizing the kinetochore microtubules.

 Activity 11.2 The Mitotic Spindle www.Life11e.com/ac11.2

There are two groups of microtubules in the spindle:

- . Polar microtubules form the framework of the spindle and run from one pole to the other.
- . Kinetochore microtubules, which form later, attach to the kinetochores on the chromosomes. The two sister chromatids in each chromosome pair become attached to kinetochore microtubules in opposite halves of the spindle (**Figure 11.10B**). This ensures that the two chromatids will eventually move to opposite poles.

Movement of the chromatids achieves the central goal of mitosis. It accomplishes the segregation of the genetic material that must occur before the cell can divide and complete the cell cycle. Prophase prepares for this movement, and the actual segregation takes place in the next three phases of mitosis.

Chromosome separation and movement are highly organized

During the next three phases of mitosis—prometaphase, metaphase, and anaphase—dramatic changes take place in the cell and the chromosomes (see [Figure 11.9](#)). During prometaphase, the nuclear envelope breaks down and spindle formation is completed. During metaphase, the chromosomes line up at the equatorial position of the cell. Now let's consider two key processes of anaphase: separation of the chromatids, and the mechanism of their actual movement toward the poles.

CHROMATID SEPARATION

The separation of chromatids occurs at the beginning of anaphase. It is controlled by an M phase cyclin–Cdk (see [Figure 11.5](#)), which activates another protein complex called the

anaphase-promoting complex (APC). Separation occurs because one subunit of the cohesin protein holding the sister chromatids together is hydrolyzed by a specific protease, appropriately called separase ([Figure 11.11](#)). A cell cycle checkpoint, often called the spindle assembly checkpoint, occurs at the end of metaphase to inhibit the APC if one of the chromosomes is not attached properly to the spindle. When all chromosomes are attached, the APC is activated and the chromatids separate. After separation the chromatids are called [daughter chromosomes](#). Note the difference between chromatids and chromosomes:

Figure 11.11 Chromatid Attachment and Separation The cohesin protein complex holds sister chromatids together at the centromere. The enzyme separase hydrolyzes cohesin at the end of metaphase, allowing the chromatids to separate into daughter chromosomes.

daughter chromosomes During mitosis, the separated chromatids from the beginning of anaphase onward.

Chromatids share a centromere.

Chromosomes have their own centromere.

CHROMOSOME MOVEMENT

The migration of the two sets of daughter chromosomes to the poles of the cell is a highly organized, active process. Three mechanisms operate to move the chromosomes along. First, the kinetochores contain molecular motor proteins, including kinesins and cytoplasmic dynein (see [Figures 5.18](#) and [5.19](#)), which use energy from ATP hydrolysis to do the work of moving the chromosomes along the microtubules. Second, the kinetochore microtubules shorten, drawing the chromosomes toward them. Third, the centrosomes move apart, aiding in separation. The last stage of mitosis is telophase, when the spindle disappears and a nuclear envelope forms around each set of chromosomes (see [Figure 11.9](#)). Finally, the cytoplasms of the two daughter cells separate during cytokinesis: the last stage of cell division.

Media Clip 11.1 Mitosis: Live and Up Close www.Life11e.com/mc11.1

Cytokinesis divides the cytoplasm

Cytokinesis divides the cell's cytoplasm after nuclear division in mitosis. There are substantial differences between the process in animal and plant cells. In animal cells, cytokinesis begins with a furrowing of the cell membrane, as if an invisible thread were cinching the cytoplasm between the two nuclei ([Figure 11.12A](#)). This contractile ring is composed of microfilaments of actin and associated myosin (see [Figure 5.15](#)), which form a ring on the cytoplasmic surface of the cell membrane. These two proteins interact to produce a contraction, pinching the cell in

two. The microfilaments assemble rapidly from actin monomers that are present in the interphase cytoskeleton.

(A) Cytokinesis of an animal cell

Contractile ring

50 μm

The contractile ring has completely separated the cytoplasms of these two daughter cells, although their surfaces remain in contact.

(B) Cytokinesis of a plant cell

Figure 11.12 Cytokinesis Differs in Animal and Plant Cells (A) A sea urchin zygote (fertilized egg) that has just completed cytokinesis at the end of the first cell division of its development into an embryo. **(B)** A dividing plant cell in late telophase. Plant cells divide differently from animal cells because plant cells have cell walls.

The plant cell cytoplasm divides differently because plants have rigid cell walls. In plant cells, as the spindle breaks down after mitosis, membranous vesicles derived from the Golgi apparatus appear along the plane of cell division, roughly midway between the two daughter nuclei. The vesicles are propelled along microtubules by the motor protein kinesin, and fuse to form a new cell membrane. At the same time they contribute their contents to a cell plate, which is the beginning of a new cell wall ([Figure 11.12B](#)).

Following cytokinesis, each daughter cell contains all the components of a complete cell. A precise distribution of chromosomes is ensured by mitosis. In contrast, organelles such as ribosomes, mitochondria, and chloroplasts do not need to be distributed equally between daughter cells, as long as some of each are present in each cell. Accordingly, there is no mechanism with a precision comparable to that of mitosis to provide for their equal allocation to daughter cells.

11.3 recap

Mitosis is the ordered division of a eukaryotic cell nucleus into two nuclei with identical sets of chromosomes. The process of mitosis, while continuous, can be viewed as a series of events (prophase, prometaphase, metaphase, anaphase, and telophase). Once two nuclei have formed, the cell divides into two cells by cytokinesis.

learning outcomes

You should be able to:

- Show how packaging of DNA into chromosomes ensures that each daughter cell receives an entire set.
- Explain how cell structures are involved in mitosis.
- Describe cytokinesis.

-
1. Differentiate among a chromosome, a chromatid, and a daughter chromosome, and identify their roles in a dividing cell.
 2. What are the various levels of “packing” by which the genetic information contained in linear DNA is condensed during prophase?
 3. Taxol is an anticancer drug that binds to microtubules, preventing them from adding or removing subunits and causing them to form bundles. How do you think this drug works to stop cancer? Is Taxol specific to cancer cells?
 4. How does cytokinesis differ in plant and animal cells?
 5. How would the cell cycle be affected if there were a non-functional cohesin protein?

Mitosis results in two cells that are genetically identical. But there is another eukaryotic cell division process, meiosis, that results in genetic diversity. In the next section we will discuss the roles of mitosis and meiosis in sexual reproduction, and then turn to the details of meiosis in [Key Concept 11.5](#).

*** connect the concepts** connect the concepts As described in [Key Concept 5.3](#), microtubules are made from dimers of tubulin monomers, which can be added or subtracted rapidly to adjust the length of the microtubule.

11.4 Cell Division Plays Important Roles in the Sexual Life Cycle

The mitotic cell cycle repeats itself, and by this process a single cell can give rise to many cells with identical nuclear DNA. Meiosis, by contrast, produces just four daughter cells. Mitosis and meiosis are both involved in reproduction but in different ways: asexual reproduction involves only mitosis, whereas the sexual reproduction cycle involves both mitosis and meiosis.

***Asexual reproduction**, sometimes called vegetative reproduction, is based on the mitotic division of the nucleus. An organism that reproduces asexually may be single-celled like yeast, reproducing itself with each cell cycle, or it may be multicellular like an aspen in a forest in the Wasatch Mountains of Utah ([Figure 11.13](#)). Aspen can reproduce sexually, with male and female plants, but in many aspen stands all the trees are the same sex, and DNA analyses have shown that they are [clones](#) of a single parent organism; the offspring are genetically identical to the parent. Any genetic variation among the trees is most likely due to small environmentally caused changes in the DNA. As you will see, this small amount of variation contrasts with the extensive variation possible in sexually reproducing organisms.

Figure 11.13 Asexual Reproduction on a Large Scale In this forest, the aspen trees arose from a single tree by asexual reproduction. They are virtually identical genetically.

clone

[Gk. *klon*: twig, shoot] (1) Genetically identical cells or organisms produced from a common ancestor by asexual means. (2) To produce many identical copies of a DNA sequence by its introduction into, and subsequent asexual reproduction of, a cell or organism.

Unlike asexual reproduction, [sexual reproduction](#) results in an organism that is not identical to

its parents. Sexual reproduction requires **gametes** created by meiosis; two parents each contribute one gamete to each of their offspring. Meiosis can produce gametes—and thus offspring—that differ genetically from each other and from the parents. Because of this genetic variation, some offspring may be better adapted than others to survive and reproduce in a particular environment. While asexually reproducing organisms can have genetic diversity, meiosis generates much more diversity, which is available for natural selection and evolution.

sexual reproduction Reproduction involving the union of gametes.

gamete (gam' eet) [Gk. *gamete/gametes*: wife, husband] The mature sexual reproductive cell: the egg or the sperm.

focus your learning

Asexual reproduction occurs via mitosis whereas sexual reproduction occurs via meiosis and mitosis.

All sexual life cycles involve haploid and diploid phases.

Sexual life cycles produce haploid and diploid cells

In most multicellular organisms, the body cells that are *not* specialized for reproduction, called **somatic cells**, each contain two sets of chromosomes, which are found in pairs. One chromosome of each pair comes from each of the organism's two parents; in humans, for example, 23 of the 46 chromosomes come from the mother and 23 from the father. The members of such a **homologous pair** are similar in size and appearance. The two chromosomes in a homologous pair (called **homologs**) bear corresponding, though not identical, genetic information.

somatic cell [Gk. *soma*: body] All the cells of the body that are not specialized for reproduction. (Contrast with germ cell.)

homologous pair A pair of matching chromosomes made up of a chromosome from each of the two sets of chromosomes in a diploid organism.

homolog (1) In cytogenetics, one of a pair (or larger set) of chromosomes having the same overall genetic composition and sequence. In diploid organisms, each chromosome inherited from one parent is matched by an identical (except for mutational changes) chromosome—its homolog—from the other parent. (2) In evolutionary biology, one of two or more features in different species that are similar by reason of descent from a common ancestor.

For example, a homologous pair of chromosomes in a plant may carry different versions of a gene that controls seed shape. One homolog may carry the version for wrinkled seeds while the other may carry the version for smooth seeds. You'll see these genes in the next chapter.

There is no simple relationship between the size of an organism and the number of chromosomes in its genome. A housefly has 5 chromosome pairs and a horse has 32, but the smaller carp (a fish) has 52 pairs. Probably the highest number of chromosomes in any organism is in the fern *Ophioglossum reticulatum*, which has 1,260 (630 pairs)!

In contrast to somatic cells, gametes contain only a single set of chromosomes—that is, one homolog from each pair. The number of chromosomes in a gamete is denoted by n , and the cell is said to be **haploid**. During reproduction, two haploid gametes fuse to form a **zygote** in a

process called **fertilization**. The zygote thus has two sets of chromosomes, just as the somatic cells do in a diploid organism. Its chromosome number is denoted by $2n$, and the zygote is said to be **diploid**. Depending on the organism, the zygote may divide by either meiosis or mitosis. Either way, a new mature organism develops that is capable of sexual reproduction.

haploid (hap' loid) [Gk. *haploides*: single] Having a chromosome complement consisting of just one copy of each chromosome; designated $1n$ or n . (Contrast with diploid.)

zygote (zye' gote) [Gk. *zygotos*: yoked] The cell created by the union of two gametes, in which the gamete nuclei are also fused. The earliest stage of the diploid generation.

fertilization Union of gametes. Also known as syngamy.

diploid (dip' loid) [Gk. *diplos*: double] Having a chromosome complement consisting of two copies (homologs) of each chromosome. Designated $2n$. (Contrast with haploid.)

All sexual life cycles involve meiosis to produce haploid cells. **Figure 11.14** presents three types. In some life cycles the products of meiosis undergo cell division, resulting in a mature organism with haploid cells. Specialized cells in these organisms become gametes. In other life cycles the gametes form directly from the products of meiosis. In all cases, the gametes fuse to produce a zygote, beginning the diploid stage of the life cycle. Since the origin of sexual reproduction, evolution has generated many different versions of the sexual life cycle.

Figure 11.14 Fertilization and Meiosis Alternate in Sexual Reproduction In sexual reproduction, haploid (n) cells or organisms alternate with diploid ($2n$) cells or organisms.

Activity 11.3 Sexual Life Cycle www.Life11e.com/ac11.3

The essence of sexual reproduction is the *random selection of half of the diploid chromosome set*—one member of each genetically similar chromosome pair—to make a haploid gamete,

followed by fusion of two haploid gametes to produce a diploid cell. Both of these steps contribute to a shuffling of genetic information in the population, so that no two individuals have exactly the same genetic makeup (unless they are identical twins). The diversity provided by sexual reproduction opens up enormous opportunities for evolution.

11.4 recap

Meiosis is necessary for sexual reproduction, in which haploid gametes fuse to produce a diploid zygote. Sexual reproduction increases genetic diversity, the raw material of evolution by natural selection.

learning outcomes

You should be able to:

- Compare and contrast asexual and sexual reproduction.
 - Differentiate between haploid and diploid cells.
 - Compare and contrast sexual life cycles in different organisms.
-
1. In terms of chromosomes, how does fertilization produce a diploid organism? How would you know the cell was diploid?
 2. What general features do all sexual life cycles have in common?
 3. You have a sample of a small green plant. How would you tell if it is haploid or diploid?
 4. Diagram haplontic and diplontic life cycles, clearly showing haploid and diploid generations.

Meiosis, unlike mitosis, results in daughter cells that differ genetically from the parent cell. We will now look at the details of meiosis to see how this genetic shuffling occurs.

*** connect the concepts** connect the concepts Asexual reproduction is common in land plants, and you can learn about this in [Key Concept 37.3](#).

11.5 Meiosis Leads to the Formation of Gametes

In the last section you learned about the role and importance of meiosis in sexual reproduction. Now you'll see how meiosis produces haploid cells. Unlike the products of mitosis, the products of meiosis are genetically different from one another and from the parent cell.

Meiosis has three overall goals:

- It reduces the chromosome number from diploid ($2n$) to haploid (n).
- It ensures that each of the haploid products has a complete set of chromosomes.
- It generates genetic diversity among the products.

focus your learning

Gametes, which are the products of meiosis, are genetically different from each other and from the parent cell.

Recombination events during meiosis increase genetic variability in gametes.

Random gene combinations in gametes result from events during meiosis.

Meiotic errors and other events introduce additional genetic variation in gametes.

Meiosis reduces the chromosome number

Meiosis consists of *two* nuclear divisions that together reduce the number of chromosomes to the haploid number, in preparation for sexual reproduction. *Although the nucleus divides twice during meiosis, the DNA is replicated only once.* The events of meiosis are illustrated in [Figure 11.15](#). You should refer to it often as you read about meiosis in detail. Two unique features characterize the first nuclear division, called [meiosis I](#):

Metaphase 1

4 The homologous pairs line up on the equatorial (metaphase) plate.

Anaphase I

5 The homologous chromosomes (each with two chromatids) move to opposite poles of the cell.

Telophase I

6 The chromosomes gather into nuclei, and the original cell divides.

MEIOSIS II

Prophase II

7 The chromosomes condense again, following a brief interphase in which DNA does not replicate.

Metaphase II

8 The centromeres of the paired chromatids line up across the equatorial plates of each cell.

Anaphase II

9 The chromatids finally separate, becoming chromosomes in their own right, and move to opposite poles. Because of crossing over and independent assortment, each new cell will have a different genetic makeup.

Figure 11.15 Meiosis: Generating Haploid Cells In meiosis, four daughter nuclei are produced, each of which has half as many chromosomes as the original cell. Four haploid cells are the result of two successive nuclear divisions. The micrographs show meiosis in the male reproductive organ of a lily; the diagrams show the corresponding phases in an animal cell. (For instructional purposes, the chromosomes from one parent are colored blue and those from the other parent are red.)

 Activity 11.5 Images of Meiosis www.Life11e.com/ac11.5

meiosis I See meiosis.

- *Homologous chromosomes come together to pair* along their entire lengths. No such pairing occurs in mitosis.
- *The homologous chromosome pairs separate*, but the individual chromosomes, each consisting of two sister chromatids, remain intact. (The chromatids will separate during meiosis II.)

Like mitosis, meiosis I is preceded by an interphase with an S phase, during which each chromosome is replicated. As a result, each chromosome consists of two sister chromatids, held together by cohesin proteins. At the end of meiosis I, two nuclei form, each with half of the original chromosomes (one member of each homologous pair). Since the centromeres did not separate, these chromosomes are still composed of two sister chromatids. The sister chromatids are separated during **meiosis II**, which is *not* preceded by DNA replication. As a result, the products of meiosis I and II are four cells, each containing the haploid number of chromosomes. But these four cells are not genetically identical.

 Animation 11.2 **Meiosis** www.Life11e.com/a11.2

 Activity 11.4 **Meiosis Simulation** www.Life11e.com/ac11.4

Chromatid exchanges during meiosis I generate genetic diversity

Meiosis I begins with a long prophase I (the first three panels of [Figure 11.15](#)), during which the chromosomes change markedly. The homologous chromosomes pair by adhering along their lengths in a process called **[synapsis](#)**. (This does not usually happen in mitosis.) This pairing process lasts from prophase I to the end of metaphase I. The four chromatids of each pair of homologous chromosomes form a **[tetrad](#)**, or bivalent. For example, in a human cell at the end of prophase I there are 23 tetrads, each consisting of four chromatids. The four chromatids come from the two partners in each homologous pair of chromosomes.

synapsis (sin ap' sis) The highly specific parallel alignment (pairing) of homologous chromosomes during the first division of meiosis.

tetrad [Gk. *tettares*: four] During prophase I of meiosis, the association of a pair of homologous chromosomes or four chromatids.

Throughout prophase I and metaphase I, the chromatin continues to coil and compact, so that the chromosomes appear ever thicker. At a certain point, the homologous chromosomes begin to be pulled apart by spindle microtubules, especially near the centromeres, but they remain held together by physical attachments mediated by cohesins. Later in prophase, regions having these attachments take on an X-shaped appearance ([Figure 11.16](#)) and are called **[chiasmata](#)** (singular *chiasma*, “cross”).

Figure 11.16 Chiasmata: Evidence of Genetic Exchange between Chromatids

This micrograph shows a pair of homologous chromosomes, each with two chromatids, during prophase I of meiosis in a salamander. Two chiasmata are visible.

chiasma (kie az' muh) (plural: chiasmata) [Gk. cross] An X-shaped connection between paired homologous chromosomes in prophase I of meiosis. A chiasma is the visible manifestation of crossing over between homologous chromosomes.

A chiasma reflects an exchange of genetic material between non-sister chromatids on homologous chromosomes—what geneticists call **crossing over** (Figure 11.17). The chromosomes usually begin exchanging material shortly after synapsis begins, but chiasmata do not become visible until later, when the homologs are repelling each other. Crossing over results in **recombinant chromatids**, and it increases genetic variation among the products of meiosis by shuffling genetic information among the homologous pairs. In Chapter 12 we will explore further the genetic consequences of crossing over.

crossing over The mechanism by which linked genes undergo recombination. In general, the term refers to the reciprocal exchange of corresponding segments between two homologous chromatids.

recombinant chromatid In meiosis, a chromatid after crossing over that contains part of a sister chromatid, typically having exchanged that part with the sister chromatid.

Figure 11.17 Crossing Over Forms Genetically Diverse Chromosomes The exchange of genetic material by crossing over results in new combinations of genetic information on the recombinant chromosomes. The two different colors distinguish the

chromosomes contributed by the male and female parents.

At this point, pause and think about what is going on at the molecular level: Each chromatid is a double-stranded DNA molecule, and the homologous chromatids therefore are homologous in DNA nucleotide sequence. Breakage and reunion of DNA molecules to form recombinant chromatids involves breakage of phosphodiester bonds that hold adjacent nucleotides on DNA together (see [Figure 4.2](#)) and formation of new bonds linking DNA molecules of two homologous chromatids.

Mitosis seldom takes more than an hour or two, but meiosis can take much longer. In human males, the cells in the testis that undergo meiosis take about a week for prophase I and about a month for the entire meiotic cycle. In females, prophase I begins long before a woman's birth, during her early fetal development, resumes and proceeds to meiosis II as much as decades later, during the monthly ovarian cycle, and is completed only when fertilization occurs (see [Key Concept 42.4](#)).

During meiosis homologous chromosomes separate by independent assortment

A diploid organism has two sets of chromosomes ($2n$): one set derived from its male parent, and the other from its female parent. As the organism grows and develops, its cells undergo mitotic divisions. In mitosis, each chromosome behaves independently of its homolog, and its two chromatids are sent to opposite poles during anaphase. Each daughter nucleus ends up with $2n$ chromosomes. In meiosis, things are very different. [Figure 11.18](#) compares the two processes.

MITOSIS

Prophase I

Metaphase I

Anaphase I

Telophase I

MEIOSIS II

Meiosis II produces four haploid daughter cells that are genetically distinct.

Figure 11.18 Mitosis and Meiosis: A Comparison Meiosis differs from mitosis chiefly by the pairing of homologs and by continued association of sister chromatids at the end of metaphase I.

In meiosis I, chromosomes of maternal origin pair with their paternal homologs during synapsis. To clarify, you have two copies of chromosome 1 of the human genome in your cells. One copy came from your mother and the other from your father. In meiosis I, these two chromosome 1's pair up. And so on with the other 22 pairs of chromosomes. *Pairing of maternal and paternal homologs does not occur in mitosis.* Segregation of the homologs during meiotic anaphase I ensures that each newly formed cell receives one member of each homologous pair (see steps 4–6 of [Figure 11.15](#)). Returning to the example of chromosome 1, at the end of meiosis I in your cells, each daughter nucleus contains one copy of chromosome 1, whereas the diploid cell that began meiosis had two copies. Taking the other 22 pairs of chromosomes into account, at the end of meiosis I in humans, each of the two daughter cells has 23 of the original 46 chromosomes.

Recall that before meiosis begins each chromosome is duplicated in S phase of interphase. So the beginning cell of meiosis had four copies of each chromosomal DNA molecule. After meiosis I each daughter cell therefore has two copies. In meiosis II, each product of meiosis I divides further to form two haploid gametes, with one copy of each chromosomal DNA molecule. So the end product of meiosis II is four haploid gametes.

Crossing over is one reason for the genetic diversity among the products of meiosis; another is ***independent assortment**, whereby each haploid cell receives an entire set of genes, but only one of each pair from each parent, from the diploid cell in a random fashion. It is a matter of chance which member of a homologous pair goes to which daughter cell at anaphase I. For example, imagine there are two homologous pairs of chromosomes in the diploid parent nucleus. A particular daughter nucleus could receive the paternal chromosome 1 and the maternal chromosome 2. Or it could get paternal 2 and maternal 1, or both maternal, or both paternal. It all depends on the way in which the homologous pairs line up at metaphase I.

Note that of the four possible chromosome combinations just described, only two produce daughter nuclei with full complements of either maternal or paternal chromosome sets (apart from the material exchanged by crossing over). *The greater the number of chromosomes, the less probable it is that the original parental combinations will be reestablished, and the greater the potential for genetic diversity.* Most species of diploid organisms have more than two pairs of chromosomes. In humans, with 23 chromosome pairs, 2^{23} (8,388,608) different combinations can be produced just by the mechanism of independent assortment. Taking the extra genetic shuffling afforded by crossing over into account, the number of possible combinations is very large indeed! Crossing over and independent assortment, along with the processes that result in mutations, provide the genetic diversity needed for the differential survival and reproduction of diverse individuals—the basis of evolution by natural selection.

You have seen how meiosis I is fundamentally different from mitosis. In contrast, meiosis II is similar to mitosis in that it involves the separation of sister chromatids into daughter nuclei (see steps 7–11 in [Figure 11.15](#)). However, because of crossing over during meiosis I, the sister chromatids are not necessarily identical to one another as they would be in mitosis. Chance assortment of the chromatids during meiosis II contributes further to the genetic diversity of the meiotic products. The final products of meiosis I and meiosis II are four haploid daughter cells, each with one set (n) of chromosomes, each of which is genetically non-identical.

Meiotic errors lead to abnormal chromosome structures and numbers

In the complex processes of mitosis and meiosis, things occasionally go wrong. In meiosis I, a pair of homologous chromosomes may fail to separate, and in mitosis or meiosis II, sister chromatids may fail to separate. Conversely, homologous chromosomes may fail to remain

together during metaphase I of meiosis, and then both may migrate to the same pole in anaphase I. These are all examples of **nondisjunction**, which results in the production of aneuploid cells. **Aneuploidy** is a condition in which one or more chromosomes are either lacking or present in excess. If nondisjunction occurs during meiosis, it can lead to offspring with either one too many, or one too few, chromosomes in all of their cells (**Figure 11.19**).

aneuploidy (an' you play dee) A condition in which one or more chromosomes or pieces of chromosomes are either lacking or present in excess.

Figure 11.19 Nondisjunction Leads to Aneuploidy Nondisjunction occurs if homologous chromosomes fail to separate during meiosis I, as illustrated here, or if chromatids fail to separate during mitosis or meiosis II. The first case is shown here. The result is aneuploidy: one or more chromosomes are either lacking or present in excess. Generally, aneuploidy is lethal to the developing embryo.

There are many different causes of aneuploidy, but one cause may be a breakdown in the cohesins that keep sister chromatids and tetrads joined together during prophase. These and other proteins ensure that when the chromosomes line up at the equatorial plate at metaphase I, for example, one homolog will face one pole and the other homolog will face the other pole. If the cohesins break down at the wrong time, both homologs may go to one pole.

Aneuploidy resulting from nondisjunction during meiosis is often lethal for the affected offspring. In a few cases, the affected offspring survive but may have certain abnormalities. An example in humans is Down syndrome, which occurs when a gamete has two copies of chromosome 21. If, for example, an egg with two of these chromosomes is fertilized by a normal

sperm, the resulting zygote will have three copies of the chromosome: it will be **trisomic** for chromosome 21. A child with Down syndrome has mild to moderately impaired intellectual ability; characteristic abnormalities of the hands, tongue, and eyelids; and an increased susceptibility to cardiac abnormalities. About 1 child in 800 is born with Down syndrome. If an egg that did not receive chromosome 21 is fertilized by a normal sperm, the zygote will have only one copy: it will be monosomic for chromosome 21, and this is lethal.

trisomic Containing three rather than two members of a chromosome pair.

Trisomies and the corresponding monosomies are surprisingly common in human zygotes, with 10–30 percent of all conceptions showing aneuploidy. But most of the embryos that develop from such zygotes do not survive to birth, and those that do often die before the age of 1 year (trisomies for chromosome 21 are the viable exception). At least one-fifth of all recognized pregnancies are spontaneously terminated (miscarried) during the first 2 months, largely because of trisomies and monosomies. The actual proportion of spontaneously terminated pregnancies is certainly higher, because the earliest ones often go unrecognized.

Other abnormal chromosomal events can also occur. In a process called **translocation**, a piece of a chromosome may break away and become attached to another chromosome. For example, a large part of one chromosome 21 may be translocated to another chromosome. Individuals who inherit this translocated piece along with two normal copies of chromosome 21 will also have Down syndrome.

translocation (1) In genetics, a rare mutational event that moves a portion of a chromosome to a new location, generally on a nonhomologous chromosome. (2) In vascular plants, movement of solutes in the phloem.

The number, shapes, and sizes of the metaphase chromosomes constitute the karyotype

When cells are in metaphase of mitosis, it is often possible to count and characterize their individual chromosomes. If a photomicrograph of the entire set of chromosomes is made, the images of the individual chromosomes can be manipulated to pair them and place them in an orderly arrangement. Such a rearranged photomicrograph reveals the number, shapes, and sizes of the chromosomes in a cell, which together constitute its **karyotype** (**Figure 11.20**). In humans, karyotypes can aid in the diagnosis of chromosomal abnormalities such as trisomies or translocations, and this has led to an entire branch of medicine called cytogenetics. However, as you will see in **Chapter 15**, chromosome analysis with the microscope is replaced in some cases by direct analysis of DNA.

karyotype The number, forms, and types of chromosomes in a cell.

(A)

Centromeres (arrows) occupy characteristic positions on homologous chromosomes.

(B)

Human somatic cells are diploid with 23 pairs of chromosomes, including the sex chromosomes. This female's sex chromosomes are X and X; a male would have X and Y chromosomes.

Figure 11.20 The Human Karyotype (A) Chromosomes from a human cell in metaphase. The DNA of each chromosome pair has a specific nucleotide sequence that is stained by a particular colored dye, so that the chromosomes in a homologous pair share a distinctive color. Each chromosome at this stage is composed of two chromatids, but they cannot be distinguished. At the upper right is an interphase nucleus. (B) This karyogram, produced by computerized analysis of the image on the left, shows homologous pairs lined up together and numbered, clearly revealing the individual's karyotype.

Polyploids have more than two complete sets of chromosomes

As mentioned in [Key Concept 11.4](#), mature organisms are often either diploid (for example, most animals) or haploid (for example, most fungi). Under some circumstances, triploid ($3n$), tetraploid ($4n$), or higher-order [polyploid](#) nuclei may form. Each of these ploidy levels

represents an increase in the number of complete chromosome sets present. If there is nondisjunction of all of the chromosomes during meiosis I (see above), diploid gametes will form. This can lead to *autopolyploidy* after fertilization. Autotriploids and autotetraploids have been important in some cases in species formation. A diploid nucleus can undergo normal meiosis because there are two sets of chromosomes to make up homologous pairs, which separate during anaphase I. Similarly, a tetraploid nucleus has an even number of each kind of chromosome, so each chromosome can pair with its homolog. However, a triploid nucleus cannot undergo normal meiosis because one-third of the chromosomes would lack partners. Triploid individuals are usually sterile.

polyploid (pol' lee ploid) Possessing more than two entire sets of chromosomes.

Because polyploid nuclei have more chromosome sets, their cells tend to be larger. This has led to the use of polyploid plants in agriculture. Diploid bananas ($2n = 22$) are smaller and produce inedible seeds; triploid bananas ($3n = 33$) are larger and seedless. A similar phenomenon is seen in triploid seedless watermelon. Perhaps the best known, and certainly the most important, polyploid crop plant is wheat. In this case, hybridization occurred between species, forming new *allopolyploid* conditions:

Haploid gametes from two species (A and B) mated to form a diploid zygote (chromosomes AB).

Nondisjunction of all chromosomes occurred during mitosis in the fertilized egg, resulting in a tetraploid (AABB), which grew up to be a fertile adult.

Modern bread wheat is the result of two such events, which occurred around 8,000 to 10,000 years ago, resulting in a hexaploid. Wheat's properties of grain formation and environmental adaptation thus come from three different ancestral species. Other allopolyploid crops include cotton, oats, and sugarcane.

11.5 recap

Meiosis produces four daughter cells in which the chromosome number is reduced from diploid to haploid. Because of the independent assortment of chromosomes and the crossing over of homologous chromatids, the four products of meiosis are not genetically identical. Meiotic errors, such as the failure of a homologous chromosome pair to separate, can lead to abnormal numbers of chromosomes. Several important crop plants, such as wheat, are polyploid.

learning outcomes

You should be able to:

- Compare and contrast the phases of mitosis with the phases of meiosis.
- Justify the claim that genetic diversity results from recombination events during meiosis.
- Use a model to illustrate how independent assortment of homologous chromosomes increases genetic diversity.
- Explain how errors in meiosis can lead to unusual patterns in chromosomes.
- Describe polyploidy and explain how it develops.

- [1.](#) How do crossing over and independent assortment result in unique daughter nuclei?
- [2.](#) Compare prophase I of meiosis with prophase of mitosis. Compare anaphase I of meiosis with anaphase of mitosis.
- [3.](#) Rarely, a person is born with an extra X chromosome (XXY). How can this arise by aneuploidy?
- [4.](#) What is polyploidy, and how does it arise?

An essential role of cell division in complex eukaryotes is to replace dead cells. What causes cells to die?

***connect the concepts** Mendel proposed the concept of independent assortment after he observed the results of genetic crosses with pea plants. See [Key Concept 12.1.](#)

11.6 Cell Death Is Important in Living Organisms

Cells within a living organism can die in one of two ways. The first type of cell death, **necrosis**, occurs when cells and tissues are damaged by mechanical means or toxins, or are starved of oxygen or nutrients. Necrotic cells often swell up and burst, releasing their contents into the extracellular environment and possibly causing inflammation (see [Key Concept 41.2](#)).

Apoptosis, or programmed cell death, is a genetically determined series of events that occurs during normal developmental processes and in adult tissues as well.

necrosis (nec roh' sis) [Gk. *nekros*: death] Premature cell death caused by external agents such as toxins.

apoptosis (ap uh toh' sis) A series of genetically programmed events leading to cell death.

focus your learning

Cells die through one of two processes, necrosis or apoptosis.

Apoptosis plays a crucial role in organism development and survival.

Apoptosis occurs through a controlled series of cellular events.

Programmed cell death removes cells that do not benefit the organism

In animals, there are two possible reasons for apoptosis:

- . *The cell is no longer needed by the organism.* For example, before birth, a human fetus has weblike hands, with connective tissue between the fingers. As development proceeds, this unneeded tissue disappears as the cells undergo apoptosis in response to specific signals.
- . *The longer cells live, the more prone they are to genetic damage that could lead to cancer.* This is especially true of epithelial cells on the surface of an organism, which may be exposed to radiation or toxic substances. Such cells normally die after only days or weeks and are replaced by new cells.

The events of apoptosis are similar in many organisms. The cell becomes detached from its neighbors and its chromatin is digested by enzymes that cut the DNA (between the nucleosomes) into fragments of about 180 base pairs. The cell forms membranous lobes, or “blebs,” that break up into cell fragments ([Figure 11.21A](#)). In a remarkable example of the economy of nature, the surrounding, living cells usually ingest the remains of the dead cell by phagocytosis. Neighboring cells digest the apoptotic cell contents in their lysosomes, and the digested components are recycled.

Figure 11.21 Apoptosis: Programmed Cell Death (A) Many cells are programmed to “self-destruct” when they are no longer needed, or when they have lived long enough to accumulate a burden of DNA damage that might harm the organism. (B) Both external and internal signals stimulate caspases, the enzymes that break down specific cell constituents, resulting in apoptosis.

Q: Apoptosis is present in most organisms, with a common molecular pathway. This indicates that apoptosis is important in terms of evolution. What might be a selective advantage for apoptosis?

Apoptosis is also used by plant cells, in an important defense mechanism called the hypersensitive response. Plants can protect themselves from disease by undergoing apoptosis at the site of infection by a fungus or bacterium. With no living tissue to grow in, the invading organism is not able to spread to other parts of the plant. Because of their rigid cell walls, plant cells do not form blebs the way animal cells do. Instead, they digest their own cell contents in the vacuole and then release the digested components into the vascular system. You will learn more about this in [Chapter 38](#).

A variety of signals, either external or from inside the cell, can lead to programmed cell death ([Figure 11.21B](#)). Such signals include hormones, growth factors, viral infection, certain toxins, or extensive DNA damage. These signals activate specific receptors, which in turn activate signal transduction pathways leading to apoptosis. Some apoptotic pathways target the mitochondria, for example, by increasing the permeability of mitochondrial membranes. The cell quickly dies if its mitochondria can’t carry out cellular respiration. An important class of enzymes called **caspases** are activated during apoptosis. These enzymes are proteases that hydrolyze

target molecules in a cascade of events. The cell dies as the caspases hydrolyze proteins of the nuclear envelope, nucleosomes, cytoskeleton, and cell membrane.

caspase One of a group of proteases that catalyze cleavage of target proteins and are active in apoptosis.

11.6 recap

Cell death can occur either by necrosis or by apoptosis. Apoptosis is governed by precise molecular controls.

learning outcomes

You should be able to:

- Compare and contrast necrosis and apoptosis.
- Justify the role of apoptosis in an organism's survival.
- Describe how apoptosis is regulated.

- [1.](#) What types of events initiate necrosis, and how do these events differ from those that initiate apoptosis?
- [2.](#) In what situations is apoptosis necessary?
- [3.](#) How is apoptosis regulated?

Mitosis adds cells to organisms, and apoptosis removes them. Under normal circumstances these processes are balanced so as to benefit the organism as a whole. In the next section we will examine what happens when this balance is disturbed and cell production runs out of control.

11.7 Unregulated Cell Division Can Lead to Cancer

Perhaps no malady affecting people in the industrialized world instills more fear than cancer, and most people realize that it involves an inappropriate increase in cell numbers. One in three Americans will have some form of cancer in his or her lifetime, and at present, one in four will die of it. With 1.5 million new cases and half a million deaths in the United States annually, cancer ranks second only to heart disease as a killer.

focus your learning

Improperly controlled cell division and the ability to migrate are two characteristics that distinguish cancer cells from normal cells.

Cell cycle abnormalities play an important role in the development of cancer.

Cancer therapies are targeted to events in the cell cycle.

Cancer cells differ from normal cells in important ways

Cancer cells differ from the normal cells from which they originate in two ways:

- . Cancer cells lose control over cell division.
- . Cancer cells can migrate to other locations in the body.

Most cells in the body divide only if they are exposed to extracellular signals such as growth factors. Cancer cells do not respond to these controls, and instead divide more or less continuously, ultimately forming **tumors** (large masses of cells). By the time a physician can feel a tumor or see one on an X-ray film or CT scan, it already contains millions of cells. Tumors can be benign or malignant:

tumor [L. *tumor*: a swollen mass] A disorganized mass of cells. Malignant tumors spread to other parts of the body.

Benign tumors resemble the tissue they came from, grow slowly, and remain localized where they develop. For example, a lipoma is a benign tumor of fat cells that may arise in the armpit and remain there. Benign tumors are not cancers, but they must be removed if they impinge on an organ, obstructing its function.

Malignant tumors do not look like their parent tissue at all. A flat, specialized epithelial cell in the lung wall may turn into a relatively featureless, round, malignant lung cancer cell (**Figure 11.22**). Malignant cells often have irregular structures, such as variable nucleus sizes and shapes. This characteristic was used to identify the cells in Henrietta Lacks's tumor as malignant (see the opening investigation of this chapter).

benign A tumor that grows to a limited extent and does not spread to other parts of the body. (Contrast with malignant.)

malignant Pertaining to a tumor that can grow indefinitely and/or spread from the original site of growth to other locations in the body. (Contrast with benign.)

Figure 11.22 A Cancer Cell with its Normal Neighbors This lung cancer cell (yellow-green) is quite different from the normal lung cells surrounding it. The cancer cell can divide more rapidly than its normal counterparts, and it can spread to other organs. This form of small-cell cancer is lethal, with a 5-year survival rate of only 10 percent. Most cases are caused by tobacco smoking.

The second and most fearsome characteristic of cancer cells is their ability to invade surrounding tissues and spread to other parts of the body by traveling through the bloodstream or lymphatic ducts. When malignant cells become lodged in some distant part of the body, they go on dividing and growing, establishing a tumor at that new site. This spreading of cancer, called [metastasis](#), results in organ failures and makes the cancer very hard to treat.

metastasis Spread of cells a tumor to regions of the body away from the primary tumor.

Cancer cells lose control over the cell cycle and apoptosis

Earlier in this chapter you learned about proteins that regulate the progress of a eukaryotic cell through the cell cycle:

Positive regulators such as growth factors stimulate the cell cycle: they are like “gas pedals.”

Negative regulators such as retinoblastoma protein (RB) inhibit the cell cycle: they are like “brakes.”

Just as driving a car requires stepping on the gas pedal *and* releasing the brakes, a cell will go through a division cycle only if the positive regulators are active and the negative regulators are inactive.

In most cells, the two regulatory systems ensure that the cells divide only when needed. In cancer cells, these two processes are abnormal.

[Oncogene](#) proteins are positive regulators in cancer cells. They are derived from normal positive regulators that have become mutated to be overly active or that are present in excess,

and they stimulate the cancer cells to divide more often. Oncogene products could be growth factors, their receptors, or other components in the signal transduction pathways (see [Chapter 7](#)) that stimulate cell division. An example of an oncogene protein is a growth factor receptor in a breast cancer cell ([Figure 11.23A](#)). Normal breast cells have relatively low numbers of the human epidermal growth factor receptor HER2. So breast cells are not usually stimulated to multiply in the presence of this growth factor. In about 25 percent of breast cancers, a DNA change results in the increased production of the HER2 receptor. This results in positive stimulation of the cell cycle, and a rapid proliferation of cells with the altered DNA.

oncogene [Gk. *onkos*: mass, tumor + *genes*: born] A gene that codes for a protein product that stimulates cell proliferation. Mutations in oncogenes that result in excessive cell proliferation can give rise to cancer.

Figure 11.23 Molecular Changes in Cancer Cells In cancer, oncogene proteins become active (A) and tumor suppressor proteins become inactive (B).

Tumor suppressors are negative regulators in both cancer and normal cells, but in cancer cells they are inactive. An example is the RB protein, which when active acts at R (the

restriction point) in G1 to block the cell cycle (see [Figure 11.5](#)). In some cancer cells RB is inactive, allowing the cell cycle to proceed. Some viral proteins can inactivate tumor suppressors. For example, the human papillomavirus infects cells of the cervix and produces a protein called E7. E7 binds to the RB protein and prevents it from inhibiting the cell cycle ([Figure 11.23B](#)). Another important tumor suppressor is p53, a transcription factor that is involved in cell cycle checkpoint pathways and apoptosis. The importance of p53 as a tumor suppressor is illustrated by the fact that more than 50 percent of human tumors have mutations in the gene that encodes p53.

tumor suppressor A gene that codes for a protein product that inhibits cell proliferation; inactive in cancer cells. (Contrast with oncogene.)
--

With oncogenes (the gas pedal) and tumor suppressor genes (the brakes), it takes more than one protein to allow the cancer cell cycle to proceed. There may be several oncogenes and tumor suppressor genes involved in a single tumor. For example, two important oncogenes in mouse cells are *Myc*, whose expression stimulates the cell cycle and prevents apoptosis, and *Ras*, a signaling molecule you saw in [Chapter 7](#) (see [Figure 7.10](#)). Experiments show that it takes the expression of both of these oncogenes to set the cell cycle in motion in mouse cells and convert them into tumor cells ([Figure 11.24](#)).

Figure 11.24 Does It Take Multiple Events to Trigger the Cancer Cell Cycle?

Original Papers: Land, H., L. Parada and R. A. Weinberg. 1983. Tumorigenic conversion of primary embryo fibroblasts required at least two cooperating oncogenes. *Nature* 304: 596–602.

Sinn, E., W. Muller, P. Pattengale, I. Tepler, R. Wallace and P. Leder. 1987. Coexpression of MMTV-Hras and MMTV/c-myc genes in transgenic mice: Synergistic action of oncogenes in vivo. *Cell* 49: 465–475.

Experiments using mouse cells in the laboratory showed that the expression of more than one oncogene is required to transform a normal cell into a cancer cell.

HYPOTHESIS ► The expression of both *Ras* and *Myc* oncogenes is needed to transform normal mouse cells into tumor cells.

METHOD

RESULTS

CONCLUSION ► The expression of both *Myc* and *Ras* oncogenes is required for tumor cell formation.

A **work with the data** exercise that accompanies this figure may be assigned in **LaunchPad**.

The discovery of apoptosis (see [Key Concept 11.6](#)) changed the way biologists think about cancer. In a population of cells, the net increase in cell numbers over time (the growth rate) is a function of cells added (the rate of cell division) and cells lost (the rate of apoptosis):

$$\text{Growth rate of cell population} = \text{rate of cell division} - \text{rate of apoptosis}$$

In normal nongrowing tissues, the rate of cell division equals the rate of apoptosis, so the cell population as a whole does not grow. Cancer cells are defective in their regulation of the cell cycle, resulting in increased rates of cell division. In addition, cancer cells can lose the ability to respond to positive regulators of apoptosis (see [Figure 11.22](#)), and this results in lowered rates of cell death. Both of these defects favor an increased growth rate of the cancer cell population.

Cancer treatments target the cell cycle

The most successful and widely used treatment for cancer is surgery. While physically removing a tumor is optimal, it is often difficult for a surgeon to get all of the tumor cells. (A tumor about 1 centimeter in diameter already has a billion cells!) Tumors are generally embedded in normal tissues. Added to this is the probability that cells of the tumor may have broken off and spread to other organs. This makes it unlikely that localized surgery will be curative. So other approaches are taken to treat or cure cancer, and these generally target the cell cycle ([Figure 11.25](#)). The goal is to decrease the rate of cell division and/or increase the rate of apoptosis so that the cancer cell population decreases.

Figure 11.25 Cancer Treatment and the Cell Cycle To prevent cancer cells from dividing, physicians use combinations of therapies that attack the cell cycle at different points.

Q: How do these treatments differ from treatments based on specific targets (see [Figure 11.24](#))? Would the side effects of the two types of treatments be different?

An example of a cancer drug that targets the cell cycle is 5-fluorouracil, which blocks the synthesis of thymine, one of the four bases in DNA. The drug paclitaxel prevents the functioning of microtubules in the mitotic spindle. Both drugs inhibit the cell cycle, and apoptosis causes

tumor shrinkage. More dramatic is radiation treatment, in which a beam of high-energy radiation is focused on the tumor. DNA damage is extensive, and the cell cycle checkpoint for DNA repair is overwhelmed. As a result, the cell undergoes apoptosis. A major problem with these treatments is that they affect normal cells as well as the tumor cells. These treatments are toxic to tissues with large populations of normal dividing cells such as those in the intestine, skin, and bone marrow (where blood cells are produced).

A major effort in cancer research is to find treatments that target only cancer cells. A promising recent example is Herceptin, which targets the HER2 growth factor receptor that occurs at high levels on the surfaces of some breast cancer cells (see [Figure 11.24A](#)). Herceptin binds specifically to the HER2 receptor but does not stimulate it. This prevents the natural growth factor from binding and stimulating cell division. Because cell division is blocked and the apoptosis rate remains the same, the tumor shrinks.

11.7 recap

Cancer cells differ from normal cells in terms of their rapid cell division and their ability to spread (metastasis). Many proteins regulate the cell cycle, either positively (oncogenes) or negatively (tumor suppressors). In cancer, one or more of these proteins is altered in some way, making its activity abnormal. Radiation and many cancer drugs target genes and proteins involved in the cell cycle.

learning outcomes

You should be able to:

- Compare and contrast cancer cells and normal cells.
- Explain how regulation of the cell cycle can become disrupted in cancer cells.
- Justify the rationale for targeting events in the cell cycle as a means of treating cancer.

1. Compare cells and genes in normal tissue, malignant tumors, and benign tumors.
2. How are oncogene proteins and tumor suppressor proteins involved in cell cycle control in normal and cancer cells?
3. Cancer-treating drugs are usually given in combination to target several stages of the cell cycle. Why might this be a better approach than using a single drug?

We have now looked at the cell cycle and at cell division by binary fission, mitosis, and meiosis. We have described the normal cell cycle and how its regulation is disrupted in cancer. We have seen how meiosis produces haploid cells in sexual life cycles. In the coming chapters we will examine heredity, genes, and DNA.

investigatinglife

What controls the reproduction of cancer cells?

In normal tissues, the rate of cell division is offset by the rate of cell death. Unlike most normal cells, HeLa cells keep growing because they have a genetic imbalance that heavily favors cell reproduction over cell death. Henrietta Lacks was infected with the human papillomavirus, which stimulates cell division in cervical cells. In addition, an enzyme called telomerase, which keeps DNA

intact and prevents cell death, is overexpressed in HeLa cells. This combination of traits—increased cell division plus decreased apoptosis—leads to the extraordinary growth rate of HeLa cells.

Because HeLa cells came from a tumor, you might expect that they are still cancer cells, and that they can form a tumor. But such is not the case. They are just cell division machines. What do you think they are missing that tumor cells have?

Future directions

Knowledge of which genes are abnormal in tumors has led to the development of drugs targeted to the specific proteins that are made from these genes. In some instances, such as breast cancers expressing HER2, the results in the clinic have been extraordinary. Patients are living longer, and even being cured by these targeted drugs. Less attention has been given to the other part of the cell population equation—cell death. Many of the widely used drugs that affect the cell cycle in general (see Figure 11.26) work not just by stopping the cell cycle but by damaging cells, triggering apoptosis. But as you may know, these drugs have widespread side effects, stopping cell division and triggering apoptosis in normal cell as well as tumor cells. We know about the molecular events in apoptosis. Perhaps targeted drugs that stimulate this process only in tumor cells could be effective.

investigatinglife

What Are the Rules of Inheritance?

Red hair is the rarest natural hair color in humans, with a frequency of about 1 percent. It is most common in northern Europe, with Scotland leading at a frequency of about 15 percent. Throughout history people have attempted to find a correlation between red-headedness and other traits. Red hair and hot temper, for example, are often associated. A recent study by the Hamburg Research Institute in Germany on the sexual activity of hundreds of women came to the conclusion that redheads were having more sex than any other hair color group. Attempts have been made to prove that redheads have a lower tolerance to pain than do people with other hair color.

Given its rarity, it is not surprising that red hair was an early subject of investigation in genetics, the science of heredity. As you will see in this chapter, the foundations of modern genetics were laid late in the nineteenth century through careful experimentation on pea plants by Gregor Mendel. By the early twentieth century, biologists examining human families noticed that in most cases, red-haired children were born from (1) two red-haired parents, (2) one parent with dark hair and one with red, or (3) two dark-haired parents. This fit the pattern for recessive inheritance, in which the gene that determines red hair can be masked by a dominant gene for dark hair. Exceptions were noted, however, and how red hair is inherited was uncertain until the late 1950s, when Brenda Ellis took a genetics course from Professor Ralph Singleton at Wake Forest University in North Carolina.

After hearing her professor discuss theories about the inheritance of red hair, Ellis investigated her family tree dating back six generations, noting which relatives had red hair. She surmised that all the redheads in her family were the offspring of either two dark-haired parents or one with dark hair and one with red hair. Each of the dark-haired people had a red-haired ancestor—presumably a carrier of a gene that determines red hair. The genetic explanation that Ellis and her professor gave for the striking pattern of recessive inheritance of red hair in her family has since become widely accepted.

Sometimes, however, red hair pops up in families with no genetic history of red hair. In this chapter we'll examine various patterns of inheritance and the genetic mechanisms by which they arise.

How do inherited characteristics such as red hair skip generations?

12.1 Inheritance of Genes Follows Mendelian Laws

Genetics, the field of biology concerned with inheritance, has a long history. There is good evidence that people were deliberately breeding animals (horses) and plants (the date palm tree) for desirable characteristics as long as 5,000 years ago. The general idea was to examine the natural variation among the individuals of a species and “breed the best to the best and hope for the best.” This was a hit-or-miss method—sometimes the resulting offspring had all the good characteristics of the parents, but often they did not.

focus your learning

Two hypotheses have been proposed to explain how characteristics are passed from one generation to the next.

Mendel's crosses of pea plants led to the formulation of laws of genetic inheritance.

Mendel's laws of inheritance apply to all sexually reproducing organisms, including humans.

By the mid-nineteenth century, two theories had emerged to explain the results of breeding experiments:

- The hypothesis of *blending inheritance* proposed that gametes (sex cells such as eggs or sperm) contained hereditary determinants (what we now call genes) that blended when the gametes fused during fertilization. Like inks of different colors, the two different determinants lost their individuality after blending and could never be separated. For example, if a plant that made smooth, round seeds was crossed (bred) with a plant that made wrinkled seeds, the offspring would be intermediate between the two and the determinants for the two parental characteristics would be lost.
- The hypothesis of *particulate inheritance* proposed that each determinant had a physically distinct nature; when gametes fused in fertilization, the determinants remained intact. According to this hypothesis, if a plant that made round seeds was crossed with a plant that made wrinkled seeds, the offspring (no matter the shape of their seeds) would still contain the determinants for the two characteristics.

The story of how these competing hypotheses were tested provides a striking example of how the scientific method can be used to support one theory and reject another. In the following sections we will look in detail at experiments performed in the 1860s by an Austrian monk and scientist, Gregor Mendel, whose work clearly supported the particulate hypothesis.

Mendel's laws arose from controlled crosses of pea plants

After entering the priesthood at a monastery in Brno, in what is now the Czech Republic, Gregor Mendel was sent to the University of Vienna, where he studied biology, physics, and mathematics. He returned to the monastery in 1853 to teach. The abbot in charge had set up a small plot of land to do experiments with plants and encouraged Mendel to continue with the experiments. Over seven years, Mendel made crosses with many thousands of plants. Analysis of his meticulously gathered data suggested to him that inheritance was due to particulate factors.

Mendel presented his theories in two public lectures in 1865 and a detailed written publication in 1866, but his work was ignored by mainstream scientists until 1900. By that time, the discovery of chromosomes had suggested to biologists that genes might be carried on chromosomes. When they read Mendel's work on particulate inheritance, the biologists connected the dots between genes and chromosomes.

Mendel chose to study the common garden pea because of its ease of cultivation and the feasibility of making controlled crosses. Pea flowers have both male and female sex organs: stamens and pistils, which produce gametes that are contained within the pollen and ovules, respectively.

Pea flowers normally self-fertilize. That is, gametes of male and female are on the same flower and can combine. However, the male organs can be removed from a flower so that it can be manually fertilized with pollen from a different flower. That's what Mendel did.

There are many varieties of pea plants with easily recognizable characteristics. A **character** is an observable physical feature, such as seed shape. A **trait** is a particular form of a character, such as round or wrinkled seeds. Mendel worked with varieties with contrasting traits for seven characters such as seed shape, seed color, and flower color. These varieties were true-breeding: that is, when he crossed a plant that produced wrinkled seeds with another of the same variety, all of the offspring plants produced wrinkled seeds.

character In genetics, an observable feature, such as eye color. (Contrast with trait.)

trait In genetics, a specific form of a character: eye color is a character; brown eyes and blue eyes are traits. (Contrast with character.)

As you will see, Mendel proposed a set of hypotheses to explain the inheritance of particular pea traits, and then designed crossing experiments to test his hypotheses. He performed his crosses in the following manner:

He removed the stamens (male parts) from flowers of one parental variety so that it couldn't self-fertilize. Then he collected pollen from another parental variety and placed it on the pistils of the emasculated flowers. The plants providing and receiving the pollen were the **parental generation**, designated **P**.

In due course, seeds formed and were planted. The seeds and the resulting new plants constituted the **first filial generation**, or **F₁**. (The word "filial" refers to the relationship between offspring and parents, from the Latin *filius*, "son.") Mendel examined each F₁ plant to see which traits it bore and then recorded the number of F₁ plants expressing each trait.

In some experiments the F₁ plants were allowed to self-pollinate and produce a **second filial**

[generation](#), or F_2 . Again, each F_2 plant was characterized and counted.

parental (P) generation The individuals that mate in a genetic cross. Their offspring are the first filial (F_1) generation.

first filial generation See F_1 .

F_1 The first filial generation; the immediate progeny of a parental (P) mating.

second filial generation See F_2 .

F_2 The second filial generation; the immediate progeny of a mating between members of the F_1 generation.

Mendel's first experiments involved monohybrid crosses

The term “hybrid” refers to the offspring of crosses between organisms differing in one or more characters. In Mendel's first experiments, he crossed parental (P) varieties with contrasting traits for a single character, producing monohybrids (from the Greek *monos*, “single”) in the F_1 generation. He subsequently planted the F_1 seeds and allowed the resulting plants to self-pollinate to produce the F_2 generation. This technique is referred to as a [monohybrid cross](#).

monohybrid cross A mating in which the parents differ with respect to the alleles of only one locus of interest.

Mendel performed the same experiment for seven pea characters. You can follow his method in **Investigating Life: Mendel's Monohybrid Cross**, using seed shape as an example. When he crossed a variety that made round seeds with one that made wrinkled seeds, all of the F_1 seeds were round—it was as if the wrinkled seed trait had disappeared completely. However, when F_1 plants were allowed to self-pollinate to produce F_2 seeds, about one-fourth of the seeds were wrinkled. These two kinds of crosses were key to distinguishing the blending and particulate theories:

- The F_1 offspring were not a blend of the two traits of the parents. Only one of the traits was present (in this case, round seeds).
- Some F_2 offspring had wrinkled seeds. The trait had not disappeared because of blending.

These observations led to a rejection of the blending theory of inheritance and provided support for the particulate theory. We now know that hereditary determinants are not actually “particulate,” but they are physically distinct entities: sequences of DNA carried on chromosomes, which we now call [genes](#).

gene [Gk. *genes*: to produce] A unit of heredity. Used here as the unit of genetic function which carries the information for a polypeptide or RNA.

All seven crosses between varieties with contrasting traits gave the same kind of data ([Table 12.1](#)). In the F_1 generation only one of the two traits was seen, but the other trait reappeared in about one-fourth of the offspring in the F_2 generation. Mendel called the trait that appeared in the F_1 and was more abundant in the F_2 the **dominant** trait, and the other trait **recessive**. In the F_2 generation, the *ratio* of exhibiting dominant to plants with recessive traits was about 3:1. (To

calculate the ratios shown in [Table 12.1](#), divide the number of F₂ plants with the dominant trait by the number with the recessive trait.)

table 12.1 Mendel's Results from Monohybrid Crosses								
Parental generation phenotypes				F ₂ generation phenotypes				
	Dominant	×	Recessive		Dominant	Recessive	Total	Ratio
	Round seeds	×	Wrinkled seeds		5,474	1,850	7,324	2.96:1
	Yellow seeds	×	Green seeds		6,022	2,001	8,023	3.01:1
	Purple flowers	×	White flowers		705	224	929	3.15:1
	Inflated pods	×	Constricted pods		882	299	1,181	2.95:1
	Green pods	×	Yellow pods		428	152	580	2.82:1
	Axial flowers	×	Terminal flowers		651	207	858	3.14:1
	Tall stems (1 m)	×	Dwarf stems (0.3 m)		787	277	1,064	2.84:1

recessive In genetics, an allele that does not determine phenotype in the presence of a dominant allele. (Contrast with dominance.)

You can see in [Table 12.1](#) that for each character, Mendel counted hundreds or even thousands of F₂ seeds or plants to see how many carried each trait. As we will discuss in more detail below, the probability of a plant inheriting a particular trait is independent of the probability of another plant inheriting the same trait. If Mendel had looked at only a few F₂ progeny from the “round × wrinkled” cross, he might, by chance, have found only round seeds. Or he might have found a higher proportion of wrinkled seeds than he did. In order to discover recurring patterns and to develop his laws of inheritance, Mendel used very large numbers of plants.

Mendel went on to expand on the particulate theory. He proposed that hereditary determinants—which we will refer to as genes, although Mendel did not use that term—occur in pairs and segregate (separate) from one another during the formation of gametes. He concluded that each pea plant has two copies of the gene for each character (such as seed shape), one inherited from each parent. We now use the term **diploid** (**2n**) to describe the state of having two copies of each gene; **haploids** (**n**) have just a single copy. You saw these terms in the last chapter when you learned about the cell cycle and meiosis.

diploid (dip’ loid) [Gk. *diplos*: double] Having a chromosome complement consisting of two copies (homologs) of each chromosome. Designated **2n**. (Contrast with haploid.)

haploid (hap’ loid) [Gk. *haploeides*: single] Having a chromosome complement consisting of just one copy of each chromosome; designated **1n** or **n**. (Contrast with diploid.)

Mendel concluded that while each gamete contains one copy of each gene, the resulting

zygote contains two copies, because it is produced by the fusion of two gametes. Furthermore, he surmised that different traits arise from different forms of a gene (now called [alleles](#)) for a particular character. For example, Mendel studied two alleles for seed shape: one that resulted in round seeds and the other resulting in wrinkled seeds.

allele (a leel') [Gk. *allos*: other] The alternate form of a genetic character found at a given locus on a chromosome.

Experiments

Mendel's Monohybrid

experiment

Original Paper: The original German version of Mendel's paper, *Versuche über Pflanzen-Hybriden*, with an English translation and extensive explanatory notes, is available online: www.mendelweb.org/Mendel.plain.html

Mendel performed crosses with pea plants and carefully analyzed the outcomes to show that genetic determinants are particulate.

HYPOTHESIS ▶ When two strains of peas with contrasting traits are bred, their characteristics are irreversibly blended in succeeding generations.

METHOD

Parental (P) seeds

Growth

Growth

1 P plants are cross-pollinated.

Parental (P) plants

F₁ seeds

F₁ seeds are all round.

2 Plant a round F₁ seed.

F₁ plant

3 Allow F₁ plants to self-pollinate.

RESULTS

F₂ seeds from F₁ plant

4 F₂ seeds: 3/4 are round, 1/4 are wrinkled (3:1 ratio).

CONCLUSION ▶ The hypothesis is rejected. There is no irreversible blending of characteristics, and a recessive trait can reappear in succeeding generations.

work with the data

Mendel's monohybrid crosses were key to his rejection of the theory of blending inheritance. While the experiment at left illustrates a monohybrid cross with round and wrinkled seeds, another of his monohybrid crosses was between true-breeding green-seeded and yellow-seeded pea plants. All of the pea plants in the F₁ generation of this cross had yellow seeds. Mendel allowed the F₁ plants to self-pollinate, and then analyzed the seed colors of the resulting F₂ generation. The table shows actual data from individual plants in the F₂ generation as reported in Mendel's paper. Mendel made mathematical calculations and presented the overall ratios for these two traits. He did not, however, perform a statistical analysis to determine whether the variations in the data reflected a general pattern of inheritance or were simply due to chance.

QUESTIONS

1. Use the hypothesis that the ratio of yellow to green seeds in the F₂ generation would be 3:1 and perform a chi-square test to analyze the results for each plant in the table (refer to Appendix B for information about the chi-square test). What can you conclude about this hypothesis from the individual plants? How many crosses have *P*-values > 0.05?
2. Now total the data from all the plants and rerun the chi-square analysis. What can you conclude? What does your analysis indicate about the need for using a large number of organisms in studies of genetics?

Plant	Seed color	
	Yellow	Green
1	25	11
2	32	7
3	14	5
4	70	27
5	24	13
6	20	6
7	32	13
8	44	9
9	50	14
10	44	18

A similar **work with the data** exercise may be assigned in LaunchPad.

An organism that is **homozygous** for a gene has two alleles that are the same (for example, two copies of the allele for round seeds).

An organism that is **heterozygous** for a gene has two different alleles (for example, one allele for round seeds and one allele for wrinkled seeds).

homozygous (home' oh zie' gus) [Gk. *homos*: same + *zygotos*: joined] In diploid organisms, having identical alleles of a given gene on both homologous chromosomes. An individual may be a homozygote with respect to one gene and a heterozygote with respect to another. (Contrast with hemizygous, heterozygous.)

heterozygous (het' er oh zie' gus) [Gk. *heteros*: different + *zygotos*: joined] In diploid

organisms, having different alleles of a given gene on the pair of homologs carrying that gene. (Contrast with hemizygous, homozygous.)

In a heterozygote, one of the two alleles may be dominant (such as round, R) and the other recessive (wrinkled, r). By convention, dominant alleles are designated with uppercase letters and recessive alleles with lowercase letters. Note that the terms dominant and recessive refer only to which phenotype is expressed when the two alleles are present together. They do not refer to which alleles are stronger, better, or more common.

The physical appearance of an organism is its **phenotype**. Mendel proposed that the phenotype is the result of the **genotype**, or genetic constitution, of the organism showing the phenotype. Round seeds and wrinkled seeds are two phenotypes resulting from three possible genotypes: the wrinkled seed phenotype is produced by the genotype rr , whereas the round seed phenotype is produced by either of the genotypes RR or Rr (because the R allele determines a dominant trait and the r allele determines a recessive trait).

phenotype (fee' no type) [Gk. *phanein*: to show] The observable properties of an individual resulting from both genetic and environmental factors. (Contrast with genotype.)

genotype (jean' oh type) [Gk. *gen*: to produce + *typos*: impression] An exact description of the genetic constitution of an individual, either with respect to a single trait or with respect to a larger set of traits. (Contrast with phenotype.)

Mendel's first law states that the two copies of a gene segregate

How do Mendel's theories explain the proportions of traits seen in the F_1 and F_2 generations of his monohybrid crosses? Mendel's first law—the **law of segregation**—states that *when any individual produces gametes, the two copies of a gene separate, so that each gamete receives only one copy*. Thus gametes from a parent with the RR genotype will all carry the R allele; gametes from an rr parent will all carry the r allele. Half of the gametes in an Rr individual will carry the R allele and the other half will carry r . What genotypes are produced when these gametes fuse to form the next generation? The allele combinations that will result from a cross can be predicted using a **Punnett square**. This device ensures that you consider all possible combinations of gametes when calculating expected genotype frequencies of the resulting offspring. A Punnett square looks like this:

law of segregation See segregation.

Punnett square Method of predicting the results of a genetic cross by arranging the gametes of each parent at the edges of a square.

It is a simple grid with all possible male gamete (haploid sperm) genotypes shown along the top and all possible female gamete (haploid egg) genotypes along the left side. The grid is completed by filling in each square with the diploid genotype that can be generated from each

combination of gametes.

Let's use a Punnett square to derive the progeny of an $RR \times rr$ cross ([Figure 12.1](#)). To determine the genotypes in the F_1 generation, into each square we put an R from the male gamete (a sperm cell from the pollen tube) and r from the female gamete (the egg cell). All the F_1 offspring of this cross (the F_1 generation) have the Rr genotype, which produces seeds with a round phenotype. What happens when the F_1 generation are crossed among themselves to produce the F_2 generation? Once the Punnett square is filled in, we readily see that there are four possible combinations of alleles in the F_2 generation: RR , Rr , rR , and rr (see [Figure 12.1](#)). Since R is dominant, there are three ways to get round seeds in the F_2 generation (genotype RR , Rr , or rR), but only one way to get wrinkled seeds (genotype rr). Therefore we predict a 3:1 ratio of the round and wrinkled phenotypes in the F_2 generation, remarkably close to the ratios Mendel found experimentally for all the traits he compared (see [Table 12.1](#)).

Figure 12.1 Mendel's Explanation of Inheritance Mendel concluded that inheritance

depends on discrete factors from each parent that do not blend in the offspring.

Mendel did not live to see his theories placed on a sound physical footing with the discoveries of chromosomes and DNA. Genes are now known to be sequences of DNA found on the much longer DNA molecules that make up chromosomes. With your knowledge of *meiosis, you can envision the different alleles of a gene segregating as chromosomes separate during meiosis I (**Focus: Key Figure 12.2**).

focus: key figure

Diploid Rr individual

- 1 This site on the chromosome is the locus of the gene with the alleles R and r , for seed shape.

Homologous chromosomes

Meiotic interphase

- 2 Before meiosis I, each of the homologous chromosomes replicates.

Sister chromatids

MEIOSIS I

- 3 At the end of meiosis I, the two chromosomes are segregated into separate daughter cells.

MEIOSIS II

Four haploid gametes

- 4 At the end of meiosis II, each haploid gamete contains one member of each pair of homologous chromosomes, and thus one allele for each gene.

Figure 12.2 Meiosis Accounts for the Segregation of Alleles Although Mendel had no knowledge of chromosomes or meiosis, we now know that a pair of alleles resides on homologous chromosomes, and that those alleles segregate during meiosis.

Q: Cells in a pea leaf have 14 chromosomes. How many chromosomes are actually in each gamete?

We know now that genes determine phenotypes mostly by producing proteins with particular functions, such as enzymes. In many cases a dominant gene is expressed (transcribed and translated) to produce a functional protein, while a recessive gene is mutated so that it is no longer expressed, or it encodes a mutant protein that is nonfunctional. For example, the wrinkled seed phenotype of *rr* peas is caused by the absence of an enzyme called starch branching enzyme 1 (SBE1), which is essential for starch synthesis. With less starch, the developing seed has more sucrose and this causes an inflow of water by osmosis. When the seed matures and dries out, the water is lost, leaving a shrunken seed. A single copy of the *R* allele produces enough functional SBE1 to prevent the wrinkled phenotype, which accounts for the dominance of *R* over *r*.

Mendel verified his hypotheses by performing test crosses

Mendel arrived at his laws of inheritance by developing a series of hypotheses and then designing experiments to test them. One hypothesis was that there are two possible allele combinations (*RR* or *Rr*) for seeds with the round phenotype. Mendel verified this hypothesis by performing test crosses with F_1 seeds derived from a variety of other crosses. A **test cross** is used to determine whether an individual showing a dominant trait is homozygous or heterozygous. The individual in question is crossed with an individual that is homozygous for the recessive allele—easy to identify, because all individuals with the recessive phenotype are homozygous for that trait.

test cross Mating of a dominant-phenotype individual (who may be either heterozygous or homozygous) with a homozygous-recessive individual.

The recessive homozygote for the seed shape gene has wrinkled seeds and the genotype *rr*. The individual being tested may be described initially as *R*_ because we do not yet know the identity of the second allele. We can predict two possible results:

- If the individual being tested is homozygous dominant (*RR*), all offspring of the test cross will be *Rr* and show the dominant trait (round seeds) (**Figure 12.3, left**).

Figure 12.3 Homozygous or Heterozygous?

Original Paper: The original German version of Mendel's paper, *Versuche uber Pflanzen-Hybriden*, with an English translation and extensive explanatory notes, is available online: www.mendelweb.org/Mendel.plain.html

An individual with a dominant phenotype may have either a homozygous or a heterozygous genotype. The test cross determines genotype.

HYPOTHESIS ▶ The progeny of a test cross can reveal whether an organism is homozygous or heterozygous.

METHOD

1a Test round peas of undetermined genotype...

×

1b ...by crossing them with wrinkled peas with a known genotype (homozygous recessive).

2a If the plant being tested is homozygous...

2b If the plant being tested is heterozygous...

RESULTS

3a ...then all progeny will show the dominant phenotype (round).

CONCLUSION

The plant being tested is likely homozygous.

3b ...then half the seeds from the cross will be wrinkled, and half will be round.

CONCLUSION

The plant being tested is heterozygous.

Activity 12.1 Homozygous or Heterozygous?
www.Life11e.com/ac12.1

- If the individual being tested is heterozygous (Rr), then approximately half the offspring of the test cross will be heterozygous and show the dominant trait (Rr), and the other half will be homozygous for the recessive allele (rr) ([Figure 12.3, right](#)).

Mendel obtained results consistent with both of these predictions; thus his hypothesis accurately predicted the results of his test crosses.

Mendel's second law states that copies of different genes assort independently

Now let's consider inheritance patterns involving two different genes. Consider an organism that is heterozygous for genes for seed color (yellow or green) and seed shape (round or wrinkled). In our example, the dominant R and Y alleles came from one parent, and the recessive r and y alleles came from the other parent. When this organism produces gametes, do the R and Y alleles always go together in one gamete, and the r and y alleles in another? Or can a single gamete receive one recessive and one dominant allele (R and y or r and Y)?

Mendel performed another series of experiments to answer these questions. He began with peas that differed in *two* characters: seed shape and seed color. One parental variety produced only round, yellow seeds ($RRYY$), and the other produced only wrinkled, green ones ($rryy$). A cross between these two varieties produced an F_1 generation in which all the plants were $RrYy$. Because the R and Y alleles were dominant, the F_1 seeds were all round and yellow.

Mendel continued this experiment into the F_2 generation by performing a [dihybrid cross](#)—a cross between individuals that are identical double heterozygotes. In this case, he simply allowed the F_1 plants, which were all double heterozygotes, to self-pollinate. Depending on whether the alleles of the two genes are inherited together or separately, there are two possible outcomes, as Mendel saw:

dihybrid cross A mating in which the parents differ with respect to the alleles of two loci of interest.

- *The alleles could maintain the associations they had in the parental generation.* If this were the case, the F_1 plants would produce two types of gametes (RY and ry). The F_2 progeny resulting from self-pollination of these F_1 plants would consist of *two phenotypes*: round yellow and wrinkled green in the ratio of 3:1, just as in the monohybrid cross.
- *The segregation of R from r could be independent of the segregation of Y from y —the two genes could be unlinked.* In this case, four kinds of gametes would be produced in equal numbers: RY , Ry , rY , and ry . When these gametes combine at random, they should produce an F_2 generation with *four phenotypes* (round yellow, round green, wrinkled yellow, wrinkled green). Putting these possibilities into a Punnett square, we can predict that these four phenotypes would occur in a ratio of 9:3:3:1.

The results supported the second prediction: four different phenotypes appeared in the F_2 generation in a ratio of about 9:3:3:1 ([Figure 12.4](#)). On the basis of such experiments, Mendel proposed his second law—the [law of independent assortment](#): *alleles of different genes assort independently of one another during gamete formation*. In the example above, the segregation of the R and r alleles is independent of the segregation of the Y and y alleles. Mendel's second law is now understood in the context of meiosis (see [Figure 11.15](#)): *chromosomes segregate independently* during the formation of gametes, and so do any two genes located on separate chromosome pairs (**Focus: Key** [Figure 12.5](#)).

Figure 12.4 Independent Assortment The 16 possible combinations of gametes in this dihybrid cross result in nine different genotypes. Because R and Y are dominant over r and y , respectively, the nine genotypes result in four phenotypes in a ratio of 9:3:3:1. These results show that the two genes segregate independently.

Media Clip 12.1 Mendel's Discoveries www.Life11e.com/mc12.1

focus: key figure

Figure 12.5 Meiosis Accountgametes with four different genotypes for Independent Assortment of Alleles We now know that copies of genes on different chromosomes are segregated independently during metaphase I of meiosis. Thus a parent of genotype $RrYy$ can form gametes with four different genotypes.

Animation 12.1 Independent Assortment of Alleles www.Life11e.com/a12.1

Q: A diploid heterozygote with a single gene can produce haploid gametes of only two genetically distinct types. A heterozygote with two genes can produce four genetically distinct types of gametes, as illustrated here. How many genetically distinct gametes could be produced by a heterozygote with four genes assorting independently? (Answer this without drawing a diagram!)

law of independent assortment See independent assortment.

Probability can be used to predict inheritance

One key to Mendel's success was his use of large numbers of plants. By counting many offspring from each cross, he observed clear patterns that allowed him to formulate his theories. After his work became widely recognized, geneticists began using simple probability calculations to predict the ratios of genotypes and phenotypes in the progeny of a given cross or mating. They use statistics to determine whether the actual results match the prediction (as explored in the work with the data exercise on [p. 243](#)).

You can think of probabilities by considering a coin toss. The basic conventions of probability are simple:

If an event is absolutely certain to happen, its probability is 1.

If it cannot possibly happen, its probability is 0.

All other events have a probability between 0 and 1.

There are two possible outcomes of a coin toss, and both are equally likely, so the probability of heads is $1/2$ —as is the probability of tails.

If two coins (say a penny and a dime) are tossed, each acts independently of the other ([Figure 12.6](#)). What is the probability of both coins coming up heads? In half of the tosses, the penny comes up heads, and in half of that fraction, the dime comes up heads. The probability of both coins coming up heads is $1/2 \times 1/4 = 1/8$. In general, *the probability of two independent outcomes occurring together is found by multiplying the two individual probabilities* (the [multiplication rule](#)). The multiplication rule can be seen in the results of a monohybrid cross (see [Figure 12.1](#)). After the self-pollination of an Rr F_1 plant, the probability that an F_2 plant will have the genotype RR is $1/2 \times 1/2 = 1/4$, because the chance that the sperm will have the genotype R is $1/2$, and the chance that the egg will have the genotype R is also $1/2$. Similarly, the probability of obtaining an rr offspring is also $1/4$.

1 Two coin tosses are independent events, each with an outcome probability (P) of $1/2$.

2 This outcome is the result of two independent events. The joint probability is $1/2 \times 1/2 = 1/4$ (multiplication rule).

Figure 12.6 Using Probability Calculations in Genetics Like the results of a coin toss, the probability of any given combination of alleles appearing in the offspring of a cross can be obtained by multiplying the probabilities of each event. Since a heterozygote can be formed in two ways, these two probabilities are added together.

multiplication rule The probability of two or more independent events occurring together is the product of their independent probabilities.

Probability can also be used to predict the proportions of phenotypes in a dihybrid cross. Let's see how this works for the experiment shown in [Figure 12.4](#). Using the principles we just described, you can calculate the probability of an F_2 seed being round. This is found by adding the probability of obtaining an Rr heterozygote ($12^{1/2}$) to the probability of an RR homozygote ($14^{1/4}$): a total of $34^{3/4}$ (the [addition rule](#)). By the same reasoning, the probability that a seed

will be yellow is also $3/4$. The two characters are determined by separate genes and are independent of each other, so:

addition rule The probability of one of two or more events that are mutually exclusive is the sum of their independent probabilities.

The joint probability for both round and yellow is $3/4 \times 3/4 = 9/16$.

What is the probability of F_2 seeds being both wrinkled and yellow? The probability of being yellow is again $3/4$; the probability of being wrinkled is $1/2 \times 1/2 = 1/4$, so:

The joint probability for both wrinkled and yellow is $1/4 \times 3/4 = 3/16$.

By the same reasoning:

The joint probability for both round ($3/4$) and green ($1/4$) is also $3/16$.

Finally:

The joint probability for both wrinkled and green is $1/4 \times 1/4 = 1/16$.

Looking at all four phenotypes, you can see that they are expected to occur in the ratio of 9:3:3:1.

A Punnett square or these simple probability calculations can be used to determine the *expected* proportions of offspring with particular phenotypes. In the dihybrid cross discussed above, about one-sixteenth of the F_2 seeds are expected to be wrinkled and green. But this does not mean that among 16 F_2 seeds there will always be exactly 1 wrinkled, green seed. For any toss of a coin, the probability of heads is independent of what happened in all the previous tosses. Even if you get three heads in a row, the chance of a head in the next toss is still $1/2$, and it is quite possible to toss a coin four times and get four heads. But if you toss the coin many times, you are highly likely to get heads in about half of the tosses. If Mendel had examined only a few progeny in each of his crosses, it is unlikely that he would have observed the phenotypic ratios that he did observe. It was his large sample sizes that allowed him to identify the underlying patterns of inheritance.

Mendel's laws can be observed in human pedigrees

Mendel worked out his laws by doing many planned crosses with pea plants and counting many offspring. Neither of these approaches is possible with humans, so human geneticists rely on **pedigrees**: family trees that show the occurrence of phenotypes (and alleles) in several generations of related individuals. You saw an example of this in the opening story of this chapter. On the next page is the eight-generation pedigree for red hair in Brenda Ellis's family.

pedigree The pattern of transmission of a genetic trait within a family.

Because humans have small numbers of offspring, human pedigrees do not show the clear proportions of phenotypes that Mendel saw in his pea plants. For example, when a man and a woman who are both heterozygous for a recessive allele (say, Aa) have children together, each child has a $1/4$ probability of being a recessive homozygote (aa). If this couple were to have several dozen children, about one-fourth of them would be recessive homozygotes. But the offspring of a single couple are likely to be too few to show the exact one-fourth proportion. In a

family with only two children, for example, both children could easily be aa (or Aa , or AA).

Figure 12.7A is a pedigree showing the pattern of inheritance of a rare dominant allele. The following are the key features to look for in such a pedigree:

(A) Dominant inheritance

**Generation I
(parents)**

Generation II

Generation III

(B) Recessive inheritance

**Generation I
(parents)**

Generation II

Generation III

Generation IV

Figure 12.7 Pedigree Analysis and Inheritance (A) This pedigree represents a family affected by Huntington's disease, which results from a rare dominant allele. Everyone who inherits this allele is affected. **(B)** The family in this pedigree carries the allele for albinism, a recessive trait. Because the trait is recessive, heterozygotes do not have the albino phenotype, but they can pass the allele on to their offspring. In this family, in generation III the heterozygous parents are cousins; however, the same result could occur if the parents were unrelated but heterozygous.

 Activity 12.2 Pedigree Analysis Simulation www.Life11e.com/ac12.2

Every affected person has an affected parent.

About half of the offspring of an affected parent are also affected. (This is easiest to observe among the 12 cousins in generation III.)

Compare this pattern with the one shown in [Figure 12.7B](#), which is typical for the inheritance of a rare recessive allele:

Affected people can have two parents who are not affected.

Only a small proportion of people are affected: about one-fourth of children whose parents are both heterozygotes.

In the families of individuals who have a rare recessive phenotype, it is not uncommon to find a marriage of two relatives. This observation is a result of the rarity of recessive alleles that give rise to abnormal phenotypes. For two phenotypically normal parents to have an affected child (*aa* genotype), the parents must both be heterozygous (*Aa*). If a particular recessive allele is rare in the general population, the chance of two people mating to produce offspring who are both carrying that allele is quite low. However, if that allele is present in a family, two cousins might share it (see [Figure 12.7B](#)). For this reason, studies on populations that are isolated either culturally (by religion, as with the Amish in the United States) or geographically (as on islands) have been extremely valuable to human geneticists. People in these groups are more likely to marry relatives who may carry the same rare recessive alleles.

12.1 recap

Mendel showed that genetic determinants are particulate and do not “blend” when the two gametes combine. Mendel’s first law of inheritance states that two copies of a gene

segregate during gamete formation. His second law states that genes assort independently during gamete formation. The frequencies with which different allele combinations will be expressed in offspring can be calculated with a Punnett square or using probability theory.

learning outcomes

You should be able to:

- Compare and contrast hypotheses of inheritance.
- Give examples of dominance and recessiveness.
- Explain the law of segregation.
- Predict the results of a monohybrid cross using a Punnett square.
- Use a model to illustrate the law of independent assortment.
- Apply probability concepts to predict the results of crosses.
- Apply Mendel's laws to analyze aspects of human pedigrees.

1. What results seen in the F_1 , and F_2 generations of Mendel's monohybrid cross experiments refuted the blending theory of inheritance?
2. Diagram the processes of meiosis that underlie the laws of segregation and independent assortment.
3. In guinea pigs, black body color (B) is completely dominant over albino (b). For the crosses below, give the genotypes of the parents:

Parental phenotypes	Black offspring	Albino offspring	Parental genotypes?
Black × albino	12	0	
Albino × albino	0	12	
Black × albino	5	7	
Black × black	9	3	

4. The pedigree below shows the inheritance of a rare mutant phenotype in humans, congenital cataracts (black symbols).

- a. Are cataracts inherited as an autosomal dominant trait? Autosomal recessive?
- b. Person #5 in the second generation mates with a man who does not have cataracts. Two of their four children, a boy and a girl, develop cataracts. What is the chance that their next child will be a girl with cataracts?

Mendel's laws of inheritance remain valid today; his discoveries laid the groundwork for all future

studies of genetics. Inevitably, however, we have learned that things are more complicated than they seemed at first. Let's take a look at some of these complications, beginning with the interactions between alleles.

*** connect the concepts** As illustrated in [Figure 11.15](#), homologous chromosomes separate in meiosis, which ultimately produces gametes with a haploid (n) number of chromosomes.

12.2 Alleles Can Produce Multiple Phenotypes

Over time genes accumulate changes, giving rise to new alleles. Thus there can be many alleles for a single character. In addition, alleles do not always show simple dominant–recessive relationships. Furthermore, a single allele may have multiple phenotypic effects.

focus your learning

Alleles can interact to produce intermediate phenotypes.

New alleles arise by mutation

Genes are subject to [mutations](#), which are stable, inherited changes in the genetic material. In other words, an allele can mutate to become a different allele. For example, imagine that at one time all pea plants were tall, and that this trait was attributable to a height allele, *T*. At some point, a mutation occurred in *T* that resulted in a new allele, *t*. If this [* mutation](#) were in a cell that underwent meiosis to form gametes, some of the resulting gametes would carry the *t* allele, and some offspring of this pea plant would carry the *t* allele. By creating variety, mutations provide the raw material for evolution.

mutation A change in the genetic material not caused by recombination.

Geneticists usually define one particular allele of a gene as the [wild type](#); this allele is the one that is present in most individuals in nature (“the wild”) and gives rise to an expected trait or phenotype. Other alleles of that gene, often called mutant alleles, may produce a different phenotype. The wild-type and mutant alleles reside at the same genetic [locus](#), which is their specific position on a chromosome. A genetic locus that carries a wild-type allele less than 99 percent of the time (the rest of the alleles being mutant) is said to be [polymorphic](#) (Greek *poly*, “many,” + *morph*, “form”).

wild type Geneticists’ term for standard or reference type. Deviants from this standard, even if the deviants are found in the wild, are usually referred to as mutant. (Note that this terminology is not usually applied to human genes.)

locus (low’ kus) (plural: loci, low’ sigh) In genetics, a specific location on a chromosome. May be considered synonymous with gene.

polymorphic (pol’ lee mor’ fik) [Gk. *poly*: many + *morphe*: form, shape] Coexistence in a population of two or more distinct traits.

Many genes have multiple alleles

Because of random mutations, more than two alleles of a given gene may exist in a group of individuals. Any one individual has only two alleles—one from its mother and one from its father. But among multiple individuals there may be several different alleles. In fact, there are many examples of such multiple alleles, and they often show a hierarchy of dominance. An example is

coat color in rabbits, determined by four alleles of the C gene:

- . C determines dark gray.
- . c^{chd} determines chinchilla, a lighter gray.
- . c^h determines Himalayan, where pigment is restricted to the extremities (point restricted).
- . c determines albino.

The hierarchy of dominance for these alleles is $C > C^{chd}$, $C^h > c$. Any rabbit with the C allele (paired with itself or any other allele) is dark gray, and a cc rabbit is albino. Intermediate colors result from different allele combinations, as shown in [Figure 12.8](#). As this example illustrates, multiple alleles can increase the number of possible phenotypes. At the biochemical level, these alleles determine various amounts of a pigment because of an enzyme with various levels of activity.

Possible genotypes			
CC, Cc ^{chd} , Cc ^h , Cc	c ^{chd} c ^{chd} , c ^{chd} c	c ^h c ^h , c ^h c	cc
			
Dark gray	Chinchilla	Point restricted	Albino
Phenotypes			

Figure 12.8 Multiple Alleles for Coat Color in Rabbits These photographs show the phenotypes conferred by four alleles of the C gene for coat color in rabbits. Different combinations of two alleles give different coat colors and pigment distributions.

A dramatic and serious example of multiple alleles involves the gene product targeted by certain widely used drugs designed to undermine the effects of the parasite that causes malaria in humans. There are numerous alleles of this parasite gene, some of which make the gene product insensitive to the drugs (they cannot bind to the target protein). Since the parasite is haploid, when a parasite has one of these resistance alleles and is in a human who is being treated with the drugs, that parasite will survive and reproduce while the vast majority of parasites with drug-sensitive wild-type alleles will be killed. Drug-resistant malaria causes great human suffering. The World Health Organization estimates that there are about 200 million new cases of malaria every year, over half a million of them fatal.

Dominance is not always complete

In the pairs of alleles studied by Mendel, dominance is complete in heterozygous individuals. That is, an Rr individual always expresses the R phenotype. However, many genes have alleles that are not dominant or recessive to one another. Instead, the heterozygotes show an intermediate phenotype—at first glance, that appeared to support the old blending theory of inheritance. For example, if a true-breeding eggplant that produces the familiar purple fruit is crossed with a true-breeding white eggplant, all the F₁ plants produce violet fruit, an intermediate between the two parents. However, further crosses indicate that this apparent blending phenomenon can still be explained in terms of Mendelian genetics ([Figure 12.9](#)). The purple and white alleles have not disappeared, as those colors reappear when the F₁ plants are

interbred.

Figure 12.9 Incomplete Dominance Follows Mendel's Laws An intermediate phenotype can occur in heterozygotes when neither allele is dominant. The heterozygous phenotype (here, violet fruit) may give the appearance of a blended trait, but the traits of the parental generation reappear in their original forms in succeeding generations, as predicted by Mendel's laws of inheritance.

When heterozygotes show a phenotype that is intermediate between those of the two homozygotes, the gene is said to be governed by **incomplete dominance**. In other words, neither of the two alleles is dominant. Incomplete dominance is common in nature; in fact, Mendel's study of pea-plant traits is unusual in that all the traits happened to be characterized by complete dominance.

incomplete dominance Condition in which the heterozygous phenotype is intermediate between the two homozygous phenotypes.

In codominance, both alleles at a locus are expressed

Sometimes the two alleles at a locus produce two different phenotypes that *both* appear in heterozygotes, a phenomenon called [codominance](#). Note that this is different from incomplete dominance, where the phenotype of a heterozygote is an intermediate between the phenotypes of the parents. A good example of codominance is seen in the ABO blood group system in humans (this is also an example of multiple alleles).

codominance A condition in which two alleles at a locus produce different phenotypic effects and both effects appear in heterozygotes.

Early attempts at blood transfusion frequently killed the patient. Around 1900, the Austrian scientist Karl Landsteiner mixed blood cells and serum (blood from which cells have been removed) from different individuals. He found that only certain combinations of blood and serum are compatible. In other combinations, the red blood cells from one individual form clumps in the presence of serum from the other individual, a discovery that led to our ability to administer compatible blood transfusions that do not kill the recipient.

Clumps in mixed blood form as a consequence of mechanisms of the immune system that protect the body from invasion by “nonself” molecules or organisms. Specific proteins in human serum, called antibodies, react with foreign molecules or particles. The specific part of a molecule that is recognized by an antibody is called an antigen. Oligosaccharides on the surfaces of red blood cells can function as antigens. For example, people with type A blood make the A antigen, and those in the B group make the B antigen; A and B antigens are specific oligosaccharides on the surfaces of their red blood cells. If a person with type A blood is given a transfusion of type B blood, that individual's immune system will recognize the B antigen as nonself and make antibodies against it ([Figure 12.10](#)). Likewise, a person with type B blood will make antibodies against the A antigen. However, someone with the codominant AB blood type makes *both* the A and the B antigens and will not make antibodies against either antigen. So a person with type AB blood can receive a transfusion from just about anyone. Individuals with type O blood make neither the A nor the B antigen (see [Figure 12.10](#)); they can receive blood only from a type O individual but can donate blood to individuals of any ABO blood group.

Blood type of cells	Geno-type	Blood cell types that body rejects	Blood type's reaction to added antibodies		
			Anti-A	Anti-B	
A	$I^A I^A$ or $I^A I^O$	B			Red blood cells that do not react with antibody remain evenly dispersed.
B	$I^B I^B$ or $I^B I^O$	A			
AB	$I^A I^B$	Neither A nor B			Red blood cells that react with antibody clump together (speckled appearance).
O	$I^O I^O$	A, B, and AB			

Figure 12.10 ABO Blood Reactions Are Important in Transfusions This table shows the results of mixing red blood cells of types A, B, AB, and O with serum containing anti-A or anti-B antibodies. As you look down the columns, note that each of the types, when mixed separately with anti-A and with anti-B, gives a unique pair of results; this is the basic method by which blood is typed. People with type O blood are the universal blood donors. People with type AB blood are good recipients, since they make neither type of antibody. When blood transfusions are incompatible, the reaction (clumping of red blood cells) can have severely adverse consequences for the recipient.

The oligosaccharides on the surfaces of red blood cells are made by enzymes that catalyze the formation of bonds between specific sugars. The ABO genetic locus encodes one such enzyme and has three alleles, I^A , I^B , and I^O , each producing a different version of the enzyme. The product of the I^A allele adds N-acetylgalactosamine to the end of a pre-existing oligosaccharide chain, resulting in the A antigen. The product of the I^B allele adds galactose to the same chain, making the B antigen. The I^O allele is recessive and encodes a protein that has no enzymatic activity:

Since people inherit one allele from each parent, they may have at the ABO locus any

combination of these alleles: $I^A I^B$, $I^A I^O$, $I^A I^A$, and so on. The I^A and I^B alleles are codominant because a person with both alleles makes both the A and the B antigens, and both kinds of oligosaccharide occur on their red blood cells. You'll learn more about the functions of antibodies and antigens in [Chapter 42](#).

Some alleles have multiple phenotypic effects

Mendel's principles were further extended when it was discovered that a single allele can influence more than one phenotype. In such a case, we say that the allele is **pleiotropic**. An example is the heritable human disease phenylketonuria, which causes mental retardation and reduced hair and skin pigmentation. The disease occurs in people who have a mutation in the gene for a liver enzyme that converts the amino acid phenylalanine to tyrosine. Without a functional form of this enzyme, phenylalanine builds up in the body to toxic levels, and this affects development in a variety of ways. Given what we now know about genes and their functions, it is not surprising that a gene with such an important metabolic role should have pleiotropic effects. Other examples of pleiotropy include plant and animal genes whose products affect hormone levels, since many hormones play multiple roles in the body.

12.2 recap

Genes are subject to random mutations that give rise to new alleles; thus many genes have more than two alleles within a population. Dominance is not necessarily an all-or-nothing phenomenon. Some genes have multiple effects on phenotype.

learning outcomes

You should be able to:

- Analyze genetic crosses involving incomplete dominance.
- Explain the concept of codominance.
- Distinguish between incomplete dominance, codominance, and pleiotropic effects.

1. What is the difference between codominance and incomplete dominance?
2. Explain how blood type AB results from codominance.
3. In a particular plant species, two alleles control flower color, which can be yellow, green, or blue. Crosses of these plants produce the following offspring:

Parental phenotypes	Offspring phenotypes (ratio)
Yellow × yellow	All yellow
Green × yellow	Green or yellow(1:1)
Green × blue	Blue or green (1:1)
Blue × blue	All blue

What will be the phenotype, and ratio, of the offspring of a cross of green × green?

Thus far we have discussed phenotypic characters that are affected by single genes. In many cases, however, several genes interact to determine a phenotype. To complicate things further, the physical environment may influence which genes of an individual are expressed, meaning

that phenotype is sometimes determined by both genes and the environment.

*** connect the concepts** [Key Concept 14.1](#) describes a mutation as a change in the nucleotide sequence of DNA, and [Key Concept 15.1](#) describes how various types of mutations affect phenotype in different ways.

12.3 Genes Can Interact to Produce a Phenotype

You have just seen how two alleles of the same gene can interact to produce a phenotype. Some phenotypes, such as human height, are influenced by the products of many genes, not just alleles of the same gene. We now turn to the genetics of such gene interactions.

focus your learning

One gene may affect the expression of another gene.

The environment can influence phenotype.

Epistasis (“to stand upon”) occurs when the phenotypic expression of one gene is affected by another gene. For example, two genes (*B* and *E*) encode proteins that determine coat color in Labrador retrievers:

epistasis Interaction between genes in which the presence of a particular allele of one gene determines whether another gene will be expressed.

- . Allele *B* (black pigment) is dominant to *b* (brown).
- . Allele *E* (pigment deposition in hair) is dominant to *e* (no deposition, so hair is yellow).

An *EE* or *Ee* dog with *BB* or *Bb* is black, and one with *bb* is brown. An *ee* dog is yellow regardless of the *B* gene alleles present ([Figure 12.11](#)). Because the product of the *E* allele is needed for the expression of both the *B* and the *b* alleles, *E* is said to be epistatic to *B*.

A dog with alleles B and E is black.

Black ($B\_E\_$)

A dog with alleles bb and E is brown.

Chocolate ($bbE\_$)

A dog with ee is yellow, regardless of its Bb alleles.

Yellow ($\_ee$)

Figure 12.11 Genes May Interact Epistatically Epistasis occurs when one gene alters the phenotypic effect of another gene. In Labrador retrievers, the E gene determines the expression of the B gene.

Q: A mating of a yellow and brown retriever produced a black pup. What were the possible genotypes of the parents?

Hybrid vigor results from new gene combinations and interactions

In 1876, Charles Darwin reported that when he crossed two different true-breeding, homozygous genetic strains of corn, the offspring were 25 percent taller than either of the parent strains. Darwin's observation was largely ignored for the next 30 years. In 1908, George Shull

“rediscovered” this idea, reporting that not just plant height but the weight of the corn grain produced was dramatically higher in the offspring ([Figure 12.12](#)). Agricultural scientists took note, and Shull’s paper had a lasting impact on the field of applied genetics. The cultivation of hybrid corn spread rapidly in the United States and all over the world, quadrupling grain production. The practice of hybridization has spread to many other crops and animals used in agriculture. For example, beef cattle that are crossbred are larger and live longer than cattle bred within their own genetic strain.

Figure 12.12 Hybrid Vigor in Corn Two homozygous parent lines of corn, B73 and Mo17, were crossed to produce the more vigorous hybrid line.

Farmers have known for centuries that matings among close relatives (known as [inbreeding](#)) can result in [inbreeding depression](#): reduced biological fitness arising from mating close relatives that tend to have the same recessive, sometimes deleterious, alleles. Inbreeding can produce offspring of smaller size and/or lower quality than matings between unrelated individuals. In contrast, superior qualities can arise from crossing inbred lines, a phenomenon called [hybrid vigor](#), or [heterosis](#) (short for heterozygosis).

inbreeding Breeding of two closely genetically related individuals.

inbreeding depression Reduction of fitness in the offspring of inbreeding.

hybrid vigor See heterosis.

heterosis The superior fitness of heterozygous offspring as compared with that of their dissimilar homozygous parents. Also called hybrid vigor.

The mechanism by which heterosis arises is not known but is important to understand, given how agriculture relies on heterosis for improving food production. Two competing hypotheses have been proposed. The dominance hypothesis explains the extra growth in hybrids as an absence of inbreeding depression—by the assumption that hybrids are unlikely to be homozygous for deleterious recessive alleles. The overdominance hypothesis postulates that in hybrids, new combinations of alleles from the parental strains interact with one another, resulting

in superior traits that cannot occur in the parental lines. Because many of the characters seen in hybrid species are in fact controlled by multiple genes, recent studies suggest that both dominance and overdominance can contribute to heterosis in specific characters.

The environment affects gene action

The phenotype of an individual does not result from its genotype alone. *Genotype and environment interact to determine the phenotype of an organism.* This is especially important to remember in the era of genome sequencing (covered in [Chapter 17](#)). When the sequence of the human genome was completed in 2003, it was hailed as the “book of life,” and public expectations of the benefits gained from this knowledge were (and are) high. But this kind of “genetic determinism” is wrong. You already know that environmental variables such as light, temperature, and nutrition can affect the phenotypic expression of a genotype.

A familiar example of this phenomenon involves “point restriction” coat patterns found in Siamese cats and certain rabbit breeds ([Figure 12.13](#)). These animals carry a mutant allele of a gene that controls the growth of dark fur all over the body. As a result of this mutation, the enzyme encoded by the gene is inactive at temperatures above a certain point (usually around 35°C). The animals maintain a body temperature above this point, and so their fur is mostly light. However, the extremities—feet, ears, nose, and tail—are cooler, about 25°C, so the fur on these regions is dark. These animals are all white when they are born, because the extremities were kept warm in the mother’s womb.

Figure 12.13 The Environment Influences Gene Expression The rabbit and cat express a coat pattern called “point restriction.” Their genotypes specify dark hair/fur, but the enzyme for dark color is inactive at normal body temperature, so only the

extremities—the coolest regions of the body—express the phenotype.

A simple experiment shows that the dark fur is temperature-dependent. If a patch of white fur on a point-restricted rabbit's back is removed and an ice pack is placed on the skin where the patch was, the fur that grows back will be dark. This indicates that although the gene for dark fur was expressed all along, the environment inhibited the activity of the mutant enzyme.

Two parameters describe the effects of genes and environment on the phenotype:

- **Penetrance** is the proportion of individuals in a group with a given genotype that actually show the expected phenotype. For example, many people who inherit a mutant allele of the gene *BRCA1* develop breast cancer. But, some people with the mutation do not. So the *BRCA1* allele is said to be incompletely penetrant.
- **Expressivity** is the degree to which a genotype is expressed in an individual. For example, a woman with the mutant *BRCA1* allele may develop both breast and ovarian cancer as part of the phenotype, but another woman with the same mutation may develop only breast cancer. So the mutant allele is said to have variable expressivity.

penetrance The proportion of individuals with a particular genotype that show the expected phenotype.

expressivity The degree to which a genotype is expressed in the phenotype; may be affected by the environment.

Most complex phenotypes are determined by multiple genes and the environment

Certain simple characters, such as those that Mendel studied in peas, differ in discrete, **qualitative** ways. Mendel used true-breeding parental pea plants that were either short or tall, had purple or white flowers, or had round or wrinkled seeds. But for most complex characters, such as height in humans, the phenotype varies more or less continuously over a range. Some people are short, others are tall, and many are in between the two extremes. Such variation within a population is called **quantitative**, or continuous, variation (**Figure 12.14**).

qualitative Based on observation of an unmeasured quality of a trait, as in brown vs. blue.

quantitative Based on numerical values obtained by measurement, as in quantitative data.

Figure 12.14 Quantitative Variation Quantitative variation is produced by the interaction of genes at multiple loci and the environment. These students (women [in

white] are shorter; men [in blue] are taller) show continuous variation in height that is the result of interactions between many genes and the environment.

Sometimes this variation results largely from the alleles that an individual possesses. For instance, much of human eye color is the result of a number of genes controlling the synthesis and distribution of dark melanin pigment. Dark eyes have a lot of it, brown eyes less, and green, gray, and blue eyes even less. In the latter cases, the distribution of other pigments in the eye is what determines light reflection and color.

In most cases, however, *quantitative variation is due to both genes and environment*. Height in humans certainly falls into this category. If you look at families, you often see that parents and their offspring all tend to be tall or short. However, nutrition also plays a role in height: American 18-year-olds today are about 6 percent taller than their great-grandparents were at the same age. Three generations are not enough time for mutations that would exert such a dramatic effect to spread throughout the general population, so the height difference must be due to environmental factors.

Geneticists call the genes that together determine such complex characters **quantitative trait loci**. Identifying these loci is a major challenge, and an important one. For example, the amount of grain that a variety of rice produces in a growing season is determined by many interacting genetic factors. Crop plant breeders have worked hard to decipher these factors in order to breed higher-yielding rice strains. In a similar way, human characteristics such as disease susceptibility and behavior are caused in part by quantitative trait loci. Recently, one of the many genes involved with human height was identified. The gene, *HMGA2*, has an allele that apparently has the potential to add 4 millimeters to human height.

quantitative trait loci A set of genes determining a complex character (trait) that exhibits quantitative variation (variation in amount rather than in kind).

12.3 recap

In epistasis, one gene affects the expression of another. Perhaps the most challenging problem for genetics is the explanation of complex phenotypes that are caused by many interacting genes and the environment.

learning outcomes

You should be able to:

- Analyze genetic data involving epistasis.
 - Compare and contrast penetrance and expressivity.
 - Compare and contrast quantitative and qualitative variation.
1. Explain the difference between penetrance and expressivity.
 2. How is quantitative variation different from qualitative variation?
 3. If the dominant allele *A* is necessary for hearing in humans, and another allele, *B*, located on a different chromosome, results in deafness no matter what other genes are present, what percentage of the offspring of a parental cross of *aaBb* × *Aabb* will be deaf?

In the next section we'll see how the discovery that genes occupy specific positions on

chromosomes enabled Mendel's successors to provide a physical explanation for his model of inheritance, and to provide an explanation for those cases where Mendel's second law does not apply.

12.4 Genes Are Carried on Chromosomes

There are far more genes than chromosomes. Studies of different genes that are physically linked on the same chromosome reveal inheritance patterns that are not Mendelian. These patterns have been useful for identifying genes that are linked to one another, and for determining how far apart they are on the chromosome.

focus your learning

Genes on the same chromosome are linked.

Recombinant frequencies can be used to infer gene locations on a chromosome.

The patterns of inheritance of phenotypes determined by genes on sex chromosomes differ from those of genes carried on autosomes.

Genetic linkage was first discovered in the fruit fly *Drosophila melanogaster*. Its small size, the ease with which it can be bred, its few chromosomes, and its short generation time make this animal an attractive experimental subject. Beginning in 1909, Thomas Hunt Morgan and his students at Columbia University pioneered the study of *Drosophila*, and today it remains a very important model organism for studies of genetics.

Animation 12.2 **Alleles That Do Not Assort Independently** www.Life11e.com/a12.2

Linked genes are inherited together

Some of the crosses Morgan performed with fruit flies yielded phenotypic ratios that were not in accordance with those predicted by Mendel's law of independent assortment. Morgan crossed *Drosophila* with known genotypes at two loci, *B* and *Vg*:

- . *B* (wild-type gray body) is dominant over *b* (black body).
- . *Vg* (wild-type wing) is dominant over *vg* (vestigial, a very small wing).

Morgan first made an F_1 generation by crossing homozygous dominant *BBVgVg* flies with homozygous recessives (*bbvgvg*). He then performed a test cross with the F_1 flies: *BbVgvg* × *bbvgvg*.¹ Morgan expected to see four phenotypes in a ratio of 1:1:1:1, but that is not what he observed. The body color gene and the wing size gene were not assorting independently; rather, they were usually inherited together (**Figure 12.15**).

experiment

Figure 12.15A Some Alleles Do Not Assort Independently

Original Paper: Morgan, T. H. 1912. Complete linkage in the second chromosome of *Drosophila*. *Science* 36: 719–720.

Morgan's studies showed that the genes for body color and wing size in *Drosophila* are linked, so that their alleles do not assort independently.

HYPOTHESIS ▶ Alleles for different characteristics always assort independently.

METHOD

RESULTS

Genotypes	$BbVgvg$ Gray, normal	$bbvgvg$ Black, vestigial	$Bbvgvg$ Gray, vestigial	$bbVgvg$ Black, normal
Expected phenotypes if independent assortment occurs	575	575	575	575
Observed phenotypes (number of individuals)	965	944	206	185

These are the results expected from Mendel's second law (independent assortment)...

...but the actual results were inconsistent with the law.

Nonrecombinant phenotypes Recombinant phenotypes

CONCLUSION ▶ The hypothesis is rejected. These two genes do not assort independently, but are linked (on the same chromosome).

Figure 12.15B **work with the data** follows on next page.

Figure 12.15B Some Alleles Do Not Assort Independently

Original Paper: Morgan, T. H. 1912.

Mendel's work was "rediscovered" 40 years after its publication. At that time, biologists began to find some exceptions to the rules of inheritance that Mendel had proposed. Thomas Hunt Morgan and his colleagues made dihybrid test crosses in fruit flies. They proposed that the clearest way to test for linkage was not to look at aberrations in the 9:3:3:1 phenotypic ratio expected from an $F_1 \times F_1$ cross, but to examine aberrations in the 1:1:1:1 ratio expected from an $F_1 \times$ homozygous recessive test cross (see Figure 12.3). Morgan's group then hypothesized that linkage had a physical basis, namely that genes are linked together on chromosomes and that rare crossing over during meiosis gives rise to the less frequent phenotypes. Examination of actual chromosomal events confirmed this.

QUESTIONS

1. Morgan first performed a dihybrid cross between black, normal-winged flies ($bbVgVg$) and gray, vestigial-winged flies ($BBvgvg$). The F_1 flies were interbred, yielding the F_2 phenotypes shown in the table (Experiment 1). Compare these data with the expected data in a 9:3:3:1 ratio by using the chi-square test (see Appendix B for information about the chi-square test). Are there differences, and are they significant?
2. To quantify linkage, Morgan crossed homozygous black, normal-winged females with homozygous gray, vestigial-winged males. He then crossed the F_1 females with black, vestigial-winged males. (You should note that this is not the same test cross as the one shown in the experiment in Figure 12.15A. In that case, the original parents were $BBVgVg$ and $bbvgvg$.) The results of this test cross are shown in the table (Experiment 2). Are these genes linked? If they are linked, what is the map distance between the genes? Explain why these data are so different from the data shown in Figure 12.15A.
3. In a third experiment, Morgan crossed two genetic strains of flies that were homozygous for the body color and wing genes. The F_1 flies were all gray and normal-winged, and these were interbred. The results are shown in the table (Experiment 3). What were the genotypes and phenotypes of the original parents that produced the F_1 ?

Experiment	Number of progeny showing each phenotype			
	Gray, normal	Black, normal	Gray, vestigial	Black, vestigial
1	2,316	1,146	737	0
2	578	1,413	1,117	307
3	246	9	65	18

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Morgan knew about chromosomes and meiosis. To explain the data, he proposed that the two *Drosophila* loci are on the same chromosome—that is, that they might be linked. Suppose that the *B* and *Vg* loci are indeed located on the same chromosome. Why didn't all of Morgan's F₁ flies have the parental phenotypes—that is, why didn't his cross result in gray flies with normal wings and black flies with vestigial wings, in a 1:1 ratio? If linkage were absolute—that is, if chromosomes always remained intact and unchanged—we would expect to see just those two types of progeny. However, this does not always happen.

Genes can be exchanged between chromatids and mapped

If linkage were absolute, Mendel's law of independent assortment would apply only to loci on different chromosomes. Instead, genes at different loci on the same chromosome *do* sometimes separate from one another during meiosis. Genes may recombine when two homologous chromosomes physically exchange corresponding segments during prophase I of meiosis—that is, by crossing over ([Figure 12.16](#)). As discussed in [Key Concept 11.2](#), DNA is replicated during S phase, so that by prophase I, when homologous chromosome pairs come together to form tetrads, each chromosome consists of two chromatids.

Homologous chromosomes

MEIOSIS I

MEIOSIS II

Figure 12.16 Crossing Over Results in Genetic Recombination Recombination accounts for why linked alleles are not always inherited together. Alleles at different loci on the same chromosome can be recombined by crossing over, and separated from one another. Such recombination occurs during prophase I of meiosis.

Note that one exchange event involves *only two of the four chromatids* in a tetrad, one from each member of the homologous pair, and can occur at any point along the length of the chromosome. The chromosome segments involved are exchanged reciprocally, so both chromatids involved in crossing over become recombinant (that is, each chromatid ends up with genes from both of the organism's parents). Usually several exchange events occur along the length of each homologous pair.

When crossing over takes place between two linked genes, not all the progeny of a cross have the parental phenotypes. Instead, recombinant offspring appear as well, as they did in Morgan's test cross (see [Figure 12.15](#)). They appear in proportions called **recombinant frequencies**, which are calculated by dividing the number of recombinant progeny by the total number of progeny ([Figure 12.17](#)). Recombinant frequencies will be *greater for loci that are farther apart* on the chromosome than for loci that are closer together because an exchange event is more likely to occur between genes that are far apart.

recombinant frequency The proportion of offspring of a genetic cross that have phenotypes different from the parental phenotypes due to crossing over between linked genes during gamete formation.

Figure 12.17 Recombinant Frequencies The frequency of recombinant offspring

(those with a phenotype different from either parent) can be calculated.

By calculating recombinant frequencies, geneticists can infer the locations of genes along a chromosome and generate a genetic map. Below is a map showing five genes on a fruit fly chromosome constructed using the recombination frequencies generated by test crosses involving various pairs of genes:

Recombinant frequency = $\frac{391 \text{ recombinants}}{2,300 \text{ total offspring}} = 0.17$

$$\text{Recombinant frequency} = \frac{391 \text{ recombinants}}{2,300 \text{ total offspring}} = 0.17$$

In the chromosome shown above, the recombination frequency between *y* and *w* is low, so they are close together on the map. Recombination between *y* and *v* is more frequent, so they are farther apart. The recombination frequencies are converted to map units (also called centiMorgans, cM); one map unit is equivalent to an average recombination frequency of 0.01 (1%).

***Gene sequencing** of DNA has made chromosome mapping less important in some areas of genetics research. However, mapping is still a way to verify that a particular DNA sequence corresponds with a particular phenotype. Linkage has allowed biologists to isolate genes and to identify genetic markers linked to important genes. This is important in breeding new crops and animals for agriculture, and for identifying people carrying medically significant mutations.

Linkage is revealed by studies of the sex chromosomes

In Mendel's work, reciprocal crosses always gave similar results; it did not matter whether a dominant allele was contributed by the female parent or the male parent. But in some cases, the parental origin of a chromosome does matter. For example, human males inherit a bleeding disorder called hemophilia from their mother, not from their father. To understand the types of inheritance in which the parental origin of an allele is important, we must consider the ways in which sex is determined in different species.

SEX DETERMINATION BY CHROMOSOMES

In corn, every diploid adult has both male and female reproductive structures. The tissues in these two types of structure are genetically identical, just as roots and leaves are genetically identical. Organisms such as corn, in which the same individual produces both male and female gametes, are said to be **monoecious** (Greek, "one house"). Other organisms, such as date palms and most animals, are **dioecious** ("two houses"), meaning that some individuals can produce only male gametes and others can produce only female gametes. In other words, in dioecious organisms the different sexes are different individuals.

monoecious (mo nee' shus) [Gk. *mono*: one + *oikos*: house] Pertaining to organisms in

which both sexes are “housed” in a single individual that produces both eggs and sperm. (In some plants, these are found in different flowers within the same plant.) Examples include corn, peas, earthworms, hydras. (Contrast with dioecious.)

dioecious (die eesh’ us) [Gk. *di*: two + *oikos*: house] Pertaining to organisms in which the two sexes are “housed” in two different individuals, so that eggs and sperm are not produced in the same individuals. Examples: humans, fruit flies, date palms. (Contrast with monoecious.)

In mammals and birds, sex is determined by differences in the chromosomes, but such determination operates in different ways in different groups of organisms. For example, in many animals, including mammals, sex is determined by a single pair of **sex chromosomes**, which differ from one another. The remaining chromosomes, called **autosomes**, occur in pairs in males and females. For example, in humans there are 22 pairs of autosomes in males and females, and 1 pair of sex chromosomes. The chromosomal bases for sex determination in various groups of animals are summarized in **Table 12.2**.

sex chromosome In organisms with a chromosomal mechanism of sex determination, one of the chromosomes involved in sex determination (in humans and many other animals, these are the X and Y chromosomes).

autosome Any chromosome (in a eukaryote) other than a sex chromosome.

table 12.2 Sex Determination in Animals

Animal group	Mechanism
Bees	Males are haploid, females are diploid
Fruit flies	Fly is female if ratio of X chromosomes to sets of autosomes is 1 or more
Birds	Males ZZ (homogametic), females WZ (heterogametic)
Mammals	Males XY (heterogametic), females XX (homogametic)

The sex chromosomes of female mammals consist of a pair of X chromosomes. Male mammals, by contrast, have one X chromosome and a sex chromosome that is not found in females, the Y chromosome. Females may be represented as XX (homogametic) and males as XY (heterogametic).

MALE MAMMALS PRODUCE TWO KINDS OF GAMETES

Each gamete produced by a male mammal has a complete set of autosomes, but just as each gamete carries one copy of each pair of autosomes, half carry a Y. When an X-bearing sperm fertilizes an egg, the resulting XX zygote is female; when a Y-bearing sperm fertilizes an egg, the resulting XY zygote is male.

SEX CHROMOSOME ABNORMALITIES REVEALED THE GENE THAT DETERMINES SEX
Can we determine which chromosome, X or Y, carries the sex-determining gene, and can the gene be identified? One way to determine cause (e.g., the presence of a gene on the Y chromosome) and effect (e.g., maleness) is to look at cases of biological error, in which the expected outcome does not happen.

We can learn something about the functions of X and Y chromosomes from abnormal sex chromosome arrangements resulting from nondisjunction during meiosis or mitosis (see **Key Concept 11.5**). As you will recall, nondisjunction occurs when a pair of homologous chromosomes (in meiosis I) or sister chromatids (in mitosis or meiosis II) fails to separate. As a

result, a gamete may have one too few or one too many chromosomes. If this gamete fuses with another gamete that has the full haploid chromosome set, the resulting offspring will be aneuploid, with fewer or more chromosomes than normal.

In humans, XO individuals sometimes appear. The O indicates that a chromosome is missing—that is, individuals that are XO have only one sex chromosome (an X). Human XO individuals are females who are moderately abnormal physically but normal mentally; usually they are also sterile. The XO condition in humans is called Turner syndrome. It is the only known case in which a person can survive with only one member of a chromosome pair (here, the XY pair), although most XO conceptions are spontaneously terminated early in development. XXY individuals also occur; this condition, which affects males, is called Klinefelter syndrome and results in overlong limbs and sterility.

These observations suggested that the gene controlling maleness is located on the Y chromosome. Observations of people with other types of chromosomal abnormalities helped researchers pinpoint the location of that gene:

Some women are genetically XY but lack a small portion of the Y chromosome.

Some men are genetically XX but have a small piece of the Y chromosome attached to another chromosome.

The Y fragments that are respectively missing and present in these two cases are the same and contain the maleness-determining gene, which was named *SRY* (sex-determining region on the Y chromosome).

The *SRY* gene encodes a protein involved in [primary sex determination](#)—that is, the determination of the kinds of gametes that an individual will produce and the organs that will make them (the male and female gonads). In the presence of the functional SRY protein, an embryo develops sperm-producing testes. (Notice that *italic type* is used for the name of a gene, but roman type is used for the name of a protein.) If the embryo has no Y chromosome, the *SRY* gene is absent, and thus the SRY protein is not made. In the absence of the SRY protein, the embryo develops egg-producing ovaries. In this case, a gene on the X chromosome called *DAX1* produces an antitestis factor. So the role of SRY in a male is to inhibit the maleness inhibitor encoded by *DAX1*. The SRY protein does this in male cells, but since it is not present in females, *DAX1* can act to inhibit maleness.

primary sex determination Genetic determination of gametic sex, male or female.
--

One function of the gonads is to produce hormones (such as testosterone and estrogen) that send signals to the rest of the body and control the development of [secondary sex characteristics](#). These are outward manifestations of maleness and femaleness, such as differences in body type, breast development, body hair, and voice. Secondary sex characteristics distinguish males and females but are not directly part of the reproductive system.

secondary sex characteristics Outward expression of sex determination in organs and tissues, such a body hair and stature in humans.

SEX-LINKED INHERITANCE IN FRUIT FLIES

As noted in [Table 12.2](#), sex determination in fruit flies is based on the *proportions* of sex chromosomes, because the numbers of these chromosomes can vary. But most commonly, the fruit fly genome has four pairs of chromosomes: three pairs of autosomes and (as in humans) a pair of sex chromosomes that differ in size. In this case, the female fly has two X chromosomes

and the male has only one, the other being the Y chromosome—so the female is XX and the male is XY. As in other organisms, the X and Y chromosomes are not true homologs of one another: *many genes on the X chromosome are not present on the Y*. The X chromosome of *Drosophila* was one of the first to have specific genes assigned to it.

Thomas Morgan identified a **sex-linked** gene that controls eye color in *Drosophila*. The wild-type allele of the gene confers red eyes, whereas a recessive mutant allele confers white eyes. Morgan's experimental crosses demonstrated that this eye color locus is on the X chromosome. If we abbreviate the eye color alleles as *R* (red eyes) and *r* (white eyes), the presence of the alleles on the X chromosome is designated by X^R and X^r .

sex-linked Gene that is carried on a sex chromosome, such as the X chromosome in mammals.

Morgan crossed a homozygous red-eyed female ($X^R X^R$) with a white-eyed male. The male is designated $X^r Y$ because the Y chromosome does not carry any allele for this gene. (Any gene that is present as a single copy in a diploid organism is called **hemizygous**.) All the sons and daughters from this cross had red eyes, because the red phenotype is dominant over white and all the progeny had inherited a wild-type X chromosome (X^R) from their mother (**Figure 12.18A**). This phenotypic outcome would have occurred even if the *R* gene had been present on an autosome rather than a sex chromosome. In that case, the male would have been homozygous recessive—*rr*.

hemizygous (hem' ee zie' gus) [Gk. *hemi*: half + *zygotos*: joined] In a diploid organism, having only one allele for a given trait, typically the case for X-linked genes in male mammals and Z-linked genes in female birds. (Contrast with homozygous, heterozygous.)

Figure 12.18 Eye Color Is a Sex-Linked Trait in *Drosophila* Morgan demonstrated that a mutant allele that causes white eyes in *Drosophila* is carried on the X chromosome. Note that in this case, the reciprocal crosses do not have the same results.

Q: If a red-eyed female was crossed with a white-eyed male and there were white-eyed males in the offspring, what was the genotype of the red-eyed female?

When Morgan performed the reciprocal cross, in which a white-eyed female (X^rX^r) was mated with a red-eyed male (X^RY), the results were unexpected: Instead of all offspring being heterozygous with red eyes, *all the sons were white-eyed and all the daughters were red-eyed* (**Figure 12.18B**). The sons from the reciprocal cross inherited their only X chromosome from their white-eyed mother and were therefore hemizygous for the white allele. The daughters, however, got an X chromosome bearing the r allele from their mother and an X chromosome bearing the R allele from their father; therefore they were red-eyed heterozygotes. When these heterozygous females were mated with red-eyed males, half their sons had white eyes but all their daughters had red eyes. Together, these results showed that eye color was carried on the X chromosome and not on the Y.

These and other experiments led to the term **sex-linked inheritance**: inheritance of a gene that is carried on a sex chromosome. (This term is somewhat misleading because “sex-linked” inheritance is not really linked to the sex of an organism—after all, both males and females carry X chromosomes.) In mammals, the X chromosome is larger and carries more genes than the Y. For this reason, most examples of sex-linked inheritance involve genes that are carried on the X chromosome.

sex-linked inheritance Pattern of inheritance characteristic of genes located on the sex chromosomes of organisms having a chromosomal mechanism for sex determination.

Many sexually reproducing species, including humans, have sex chromosomes. As in most fruit flies, human males are XY, females are XX, and relatively few of the genes that are present on the X chromosome are present on the Y. Pedigree analyses of X-linked recessive phenotypes like the one in **Figure 12.19** reveal the following patterns (compare with the pedigrees of non-X-linked phenotypes in **Figure 12.7**):

Figure 12.19 Red-Green Color Blindness Is a Sex-Linked Trait in Humans The mutant allele for red-green color blindness is expressed as an X-linked recessive trait, and therefore is always expressed in males when they carry that allele.

The phenotype appears much more often in males than in females, because only one copy of the rare allele is needed for its expression in males, whereas two copies must be present in females.

A male with the mutation can pass it on only to his daughters; all his sons get his Y chromosome.

Daughters who receive one X-linked mutation are heterozygous carriers. They are phenotypically normal, but they can pass the mutant allele to their sons or daughters. On average, half their children will inherit the mutant allele since half of their X chromosomes carry the normal allele.

The mutant phenotype can skip a generation if the mutation passes from a male to his daughter (who will be phenotypically normal) and then to her son.

12.4 recap

Simple Mendelian ratios are not observed when genes are linked on the same chromosome. Linkage results in atypical frequencies of phenotypes in the offspring from a test cross. Calculating recombination frequencies between genes can lead to a genetic map of the genes. Sex linkage in humans refers to genes on one sex chromosome (usually the X) that have no counterpart on the other sex chromosome.

learning outcomes

You should be able to:

- Describe evidence that genes on the same chromosome are linked.
- Use a model to illustrate how recombinant frequencies relate to gene locations on a chromosome.

- Analyze data involving gene linkage.
- Analyze data involving sex-linked genes.
- Construct a diagram to illustrate differences between sex-linked and autosomal genes.

1. Describe the concept of genetic linkage and its implications in genetic crosses.
2. Using a diagram of a chromosome, illustrate how the physical distance that separates genes on a chromosome affects their recombination frequency.
3. Use a Punnett square to show why red-green colorblindness is more common in males than in females.
4. How does a sex-linked gene behave differently in genetic crosses from a gene on an autosome?
5. Sometimes scientists get lucky. Consider Mendel's dihybrid cross shown in [Figure 12.4](#). Peas have a haploid number of seven chromosomes, so many of their genes are linked. What would Mendel's results have been if the genes for seed color and seed shape were linked with a map distance of 10 units? Now, consider Morgan's fruit flies (see [Figure 12.17](#)). Suppose that the genes for body color and wing shape were not linked. What results would Morgan have obtained?
6. In *Drosophila*, three autosomal genes have alleles as follows: Gray body color (B) is dominant over black (b).
Normal wings (VG) is dominant over vestigial (vg).
Red eye (R) is dominant over sepia (r).
Two crosses were performed, with the following results:

Cross I:	Parents: heterozygous red, normal x sepia, vestigial
Offspring:	131 red, normal
	120 sepia, vestigial
	122 red, vestigial
	127 sepia, normal
Cross II:	Parents: heterozygous gray, normal x black, vestigial
Offspring:	236 gray, normal
	253 black, vestigial
	50 gray, vestigial
	61 black, normal

Are any of the three genes linked on the same chromosome? If so, what is the distance between the linked genes (in map units)?

The genes we've discussed so far in this chapter are all in the cell nucleus. You might be surprised to learn that other organelles, including mitochondria and plastids, also carry genes. What are these genes, and how are they inherited?

¹ Do you recognize this type of cross? It is a test cross for the two gene pairs; see [Figure 12.3](#)

*** connect the concepts** As described in [Key Concept 17.1](#), gene sequencing techniques reveal the nucleotide sequence of genes and identify where genes begin and end on the chromosome.

12.5 Some Eukaryotic Genes Are Outside the Nucleus

The nucleus is not the only organelle in a eukaryotic cell that carries genetic material.

***Mitochondria and plastids** contain small numbers of genes. For example, in humans there are about 21,000 genes coding for proteins in the nuclear genome and 37 in the mitochondrial genome. Plastid genomes are about five times larger than those of mitochondria.

focus your learning

Mitochondria and plastids contain genes that follow inheritance patterns that differ from inheritance patterns of nuclear genes.

The inheritance of organelle genes differs from that of nuclear genes for several reasons:

In most organisms, mitochondria and/or plastids are inherited only from the female. As you will learn in [Chapter 43](#), eggs contain abundant cytoplasm and organelles, but the only part of the sperm that survives to take part in the union of haploid gametes is the nucleus. So you have inherited your mother's mitochondria (with their genes), but not your father's.

There may be hundreds of mitochondria and/or plastids in a cell. So a cell is not diploid for organelle genes.

Organelle genes tend to mutate at much faster rates than nuclear genes, so organelle genes often have multiple alleles.

Although most genes for organelle proteins are in the nucleus, several of the genes carried by cytoplasmic organelles are important for organelle assembly and function, and mutations of these genes can have profound effects on the organism. The phenotypes resulting from such mutations reflect the organelles' roles. For example, in plants and some photosynthetic protists, certain plastid gene mutations affect the proteins that assemble chlorophyll molecules into photosystems. These mutations result in a phenotype that is essentially white instead of green. The inheritance of this phenotype follows a non-Mendelian, maternal pattern ([Figure 12.20](#)). Mitochondrial gene mutations that affect the respiratory chain result in less ATP production. In animals, these mutations have particularly noticeable effects in tissues with high energy requirements, such as the nervous system, muscles, and kidneys.

Figure 12.20 Cytoplasmic Inheritance In four o'clock plants, leaf color is inherited through the female plant only. The white leaf color is caused by a chloroplast mutation.

12.5 recap

Genes in the genomes of organelles, specifically plastids and mitochondria, do not behave in a Mendelian fashion.

learning outcomes

You should be able to:

- Predict inheritance patterns of genes present in organelles.

1. A disease called Leber's hereditary optic neuropathy is caused by a mutation in a gene carried on mitochondrial DNA. What would be the phenotype of their first child if a man with this disease mated with a woman who did not have the disease? What would be the result if the wife had the disease and the husband did not?

Mendel and those who followed him focused on eukaryotes, with diploid organisms and haploid gametes. A half-century after the rediscovery of Mendel's work, a process that allows genetic recombination was discovered in prokaryotes as well. We will now turn to that process.

*** connect the concepts** [Key Concept 5.5](#) describes the endosymbiotic theory, which proposes that some organelles — particularly mitochondria and plastids—may be descended from prokaryotes that were engulfed by other, larger cells.

12.6 Prokaryotes Can Transmit Genes by Mating

As described in [Chapter 5](#), prokaryotic cells lack nuclei; they contain their genetic material mostly as single chromosomes in central regions of their cells. Prokaryotes reproduce asexually by binary fission, a process that gives rise to progeny that are virtually identical genetically. That is, the offspring of cell reproduction in prokaryotes constitute a clone (see [Chapter 11](#)). You might expect, therefore, that there is no way for individuals of these organisms to exchange genes, as in sexual reproduction. But mutations do occur in prokaryotes just as they do in eukaryotes, and the resulting new alleles increase genetic diversity. In addition, it turns out that prokaryotes do have a sexual process for transferring genes between cells.

focus your learning

Prokaryotes use conjugation to exchange genetic material on plasmids.

Bacteria exchange genes by conjugation

To illustrate the kind of experiment that led to the discovery of bacterial DNA transfer, consider two strains of the bacterium *E. coli* with different alleles for each of six genes. One strain carries the dominant (wild-type) alleles for three of the genes and the recessive (mutant) alleles for the other genes. This situation is reversed in the other strain. Simply put, the two strains have the following genotypes (remember that bacteria are haploid and thus have only one copy of each gene):

ABCdef and *abcDEF*

where capital letters indicate wild-type alleles and lowercase letters indicate mutant alleles.

When the two strains are grown together in the laboratory, most of the cells produce clones. That is, almost all of the cells that grow have the original genotypes. However, out of millions of bacteria, a few occur that have the genotype

ABCDEF

How could these completely wild-type bacteria arise? One possibility is mutation: in the *abcDEF* bacteria, the *a* allele could have mutated to A, the *b* allele to B, and the *c* allele to C. The problem with this explanation is that a mutation at any particular point in an organism's DNA sequence is a very rare event. The probability of all three events occurring in the same cell is extremely low—much lower than the actual rate of appearance of cells with the ABCDEF genotype. So the mutant cells must have acquired wild-type genes some other way—and this turns out to be the transfer of DNA between cells.

Electron microscopy shows that genetic transfers between bacteria can happen via physical contact between the cells ([Figure 12.21A](#)). Contact is initiated by a thin projection called a [sex pilus](#) (plural *pili*), which extends from one cell (the donor), attaches to another (the recipient), and draws the two cells together. Genetic material can then pass from the donor cell to the recipient through a thin cytoplasmic bridge called a conjugation tube. There is no reciprocal transfer of DNA from the recipient to the donor. This process is referred to as [bacterial conjugation](#).

(A)

(B)

Figure 12.21 Bacterial Conjugation and Recombination (A) Sex pili draw two bacteria into close contact, so that a cytoplasmic conjugation tube can form. DNA is transferred from one cell to the other via the conjugation tube. (B) DNA from a donor cell can become incorporated into a recipient cell's chromosome through crossing over

sex pilus A thin connection between two bacteria through which genetic material passes during conjugation.

bacterial conjugation See conjugation.

Once the donor DNA is inside the recipient cell, it can recombine with the recipient cell's genome. In much the same way that chromosomes pair up, gene for gene, in prophase I of meiosis, the donor DNA can line up beside its homologous genes in the recipient, and crossing over can occur. Some of the genes from the donor can become integrated into the genome of the recipient, thus changing the recipient's genetic constitution ([Figure 12.21B](#)). When the recipient cells proliferate, the integrated donor genes are passed on to all progeny cells.

Bacterial conjugation is controlled by plasmids

In addition to their main chromosome, many bacteria harbor additional smaller, circular DNA molecules called [plasmids](#), which replicate independently of the main chromosome. [*Plasmids](#) typically contain at most a few dozen genes, which may fall into one of several categories:

plasmid A DNA molecule distinct from the chromosome(s); that is, an extrachromosomal element; found in many bacteria. May replicate independently of the chromosome.

Genes for unusual metabolic capacities. For example, bacteria carrying plasmids that confer the ability to break down hydrocarbons can be used to clean up oil spills.

Genes for antibiotic resistance. Plasmids carrying genes for antibiotic resistance are called R factors, and since they can be transferred between bacteria via conjugation, they are a major threat to human health.

Genes that confer the ability to make a sex pilus.

During bacterial conjugation it is usually plasmids that are transferred from one bacterium to another ([Figure 12.22](#)). A single strand of the donor plasmid is transferred to the recipient, and then synthesis of a complementary DNA strand results in two complete copies of the plasmid, one in the donor and one in the recipient.

Figure 12.22 Gene Transfer by Plasmids When plasmids enter a cell via conjugation, their genes can be expressed in the recipient cell.

12.6 recap

Although they are haploid and reproduce asexually, prokaryotes have the ability to transfer genes from one cell to another. These genes are usually carried on small, circular DNA molecules called plasmids, but chromosomal DNA is sometimes transferred as well.

learning outcomes

You should be able to:

- Outline the steps involved in the transfer of genetic material by bacterial conjugation.
- Explain the significance of mating and genetic recombination in prokaryotes.

1. Discuss the genetic significance of mating and recombination in bacteria.
2. What is the potential consequence of a plasmid being integrated into the main

▶ investigatinglife

QA How do inherited characteristics such as red hair skip generations?

Hair color is determined by the pigment melanin, which is synthesized from the amino acid tyrosine (see [Table 3.2](#)). There are two forms of this pigment, eumelanin (black or brown, depending on how much accumulates) and pheomelanin (red or blond). Pigment production is an excellent example of intercellular signaling at work (see [Chapter 7](#)). Skin cells called melanocytes have a receptor, MC1R (melanocortin 1 receptor), for the signal melanocortin. Receptor binding sets off a signal transduction pathway that activates the cells to make much more eumelanin than pheomelanin.

As is common with recessive traits, red hair results from a mutation in a gene, in this case a mutation in the *MC1R* gene, located on chromosome 16. As a recessive trait it must be inherited from both parents to cause the hair to become red. The *MC1R* gene has multiple alleles: the wild type (R), which produces a normal receptor, and three recessive (r, mutated) alleles, each of which leads to red hair.

So what happens when a person inherits two of these recessive alleles? MC1R is not expressed, so it does not bind the signal that would activate the eumelanin pathway, and pheomelanin is made instead. If enough pheomelanin accumulates, red hair results. The type of red hair that is inherited—fair, strawberry blonde, or auburn—depends on which recessive allele is inherited.

Future directions

As biologists learn more about individual genes and their alleles, they are beginning to make predictions about how gene products interact with one another and with factors in the environment. You probably know that smoking can cause lung cancer, yet there are some people who smoke a lot and don't get the disease. It turns out that these people often carry an allele that alleviates their encounter with the harmful substances in cigarette smoke. We all have genes whose products change environmental substances. In the case of cigarette smoke, the gene product of the typical allele turns the molecules in smoke into DNA-damaging, cancer-causing toxins. People who carry a mutant form of this gene are relatively resistant to getting lung cancer from smoking because the product of this mutant gene does not carry out the activation reactions. The genomes of all organisms carry such genes that are involved in environmental interaction. Describing these genes holds promise in understanding the relative contributions of environment and genetics to establishing a phenotype.

12.1 Inheritance of Genes Follows Mendelian Laws

- Physical features of organisms, or **characters**, can exist in different forms, or **traits**. A heritable trait is one that can be passed from parent to offspring. A **phenotype** is the physical appearance or other detectable characteristic of an organism; a **genotype** is the genetic constitution of the organism.

character In genetics, an observable feature, such as eye color. (Contrast with trait.)

trait In genetics, a specific form of a character: eye color is a character; brown eyes and blue eyes are traits. (Contrast with character.)

phenotype (fee' no type) [Gk. *phanein*: to show] The observable properties of an individual resulting from both genetic and environmental factors. (Contrast with genotype.)

genotype (jean' oh type) [Gk. *gen*: to produce + *typos*: impression] An exact description of the genetic constitution of an individual, either with respect to a single trait or with respect to a larger set of traits. (Contrast with phenotype.)

- The different forms of a **gene** are called **alleles**. Diploid organisms that have two identical alleles for a trait are called **homozygous**; organisms that have two different alleles for a trait are called **heterozygous**. A gene resides at a particular site on a chromosome called a **locus**.

gene [Gk. *genes*: to produce] A unit of heredity. Used here as the unit of genetic function which carries the information for a polypeptide or RNA.

allele (a leel') [Gk. *allos*: other] The alternate form of a genetic character found at a given locus on a chromosome.

homozygous (home' oh zie' gus) [Gk. *homos*: same + *zygotos*: joined] In diploid organisms, having identical alleles of a given gene on both homologous chromosomes. An individual may be a homozygote with respect to one gene and a heterozygote with respect to another. (Contrast with hemizygous, heterozygous.)

heterozygous (het' er oh zie' gus) [Gk. *heteros*: different + *zygotos*: joined] In diploid organisms, having different alleles of a given gene on the pair of homologs carrying that gene. (Contrast with hemizygous, homozygous.)

locus (low' kus) (plural: loci, low' sigh) In genetics, a specific location on a chromosome. May be considered synonymous with gene.

- Mendel's experiments included reciprocal crosses and **monohybrid crosses** between true-breeding pea plants. Analysis of his meticulously tabulated data led Mendel to propose a particulate theory of inheritance stating that discrete units (now called genes) are responsible for the inheritance of specific traits, to which both parents contribute equally.

monohybrid cross A mating in which the parents differ with respect to the alleles of only one

locus of interest.

- Mendel's first law, the [law of segregation](#), states that when any individual produces gametes, the two copies of a gene separate, so that each gamete receives only one member of the pair. Thus every individual in the F₁ inherits one copy from each parent. !!**Review** [Figure 12.1](#), **Focus:** [Key Figure 12.2](#)

law of segregation See segregation.

- Mendel used a [test cross](#) to find out whether an individual showing a dominant phenotype was homozygous or heterozygous. !!**Review** [Figure 12.3](#), [Activity 12.1](#)

test cross Mating of a dominant-phenotype individual (who may be either heterozygous or homozygous) with a homozygous-recessive individual.

- Mendel's use of [dihybrid crosses](#) to study the inheritance of two characters led to his second law: the [law of independent assortment](#). The independent assortment of chromosomes in meiosis leads to new combinations of phenotypes in the offspring of a dihybrid cross. !!**Review** [Figure 12.4](#), **Focus:** [Key Figure 12.5](#), [Animation 12.1](#)

dihybrid cross A mating in which the parents differ with respect to the alleles of two loci of interest.

law of independent assortment See independent assortment.

- Probability calculations and [pedigrees](#) help geneticists trace Mendelian inheritance patterns. Review [Figures 12.6](#), !![12.7](#), [Activity 12.2](#)

pedigree The pattern of transmission of a genetic trait within a family.

!!!!!!

► 12.2 Alleles Can Produce Multiple Phenotypes

- New alleles arise by random [mutation](#). Many genes have multiple alleles. A wild-type allele gives rise to the predominant form of a trait. When the wild-type allele is present at a locus less than 99 percent of the time, the locus is said to be [polymorphic](#). !!**Review** [Figure 12.8](#)

mutation A change in the genetic material not caused by recombination.

polymorphic (pol' lee mor' fik) [Gk. *poly*: many + *morphe*: form, shape] Coexistence in a population of two or more distinct traits.

- In [incomplete dominance](#), neither of two alleles is dominant. The heterozygous phenotype is intermediate between the homozygous phenotypes. !!**Review** [Figure 12.9](#)

incomplete dominance Condition in which the heterozygous phenotype is intermediate between the two homozygous phenotypes.

- **Codominance** exists when two alleles at a locus produce two different phenotypes that both appear in heterozygotes. !!**Review Figure 12.10**

codominance A condition in which two alleles at a locus produce different phenotypic effects and both effects appear in heterozygotes.

- An allele that affects more than one trait is said to be **pleiotropic**.

▶ 12.3 Genes Can Interact to Produce a Phenotype

- In **epistasis**, one gene affects the expression of another. !!**Review Figure 12.11**

epistasis Interaction between genes in which the presence of a particular allele of one gene determines whether another gene will be expressed.

- Environmental conditions can affect the expression of a genotype.
- **Penetrance** is the proportion of individuals in a group with a given genotype that show the expected phenotype. **Expressivity** is the degree to which a genotype is expressed in an individual.

penetrance The proportion of individuals with a particular genotype that show the expected phenotype.

expressivity The degree to which a genotype is expressed in the phenotype; may be affected by the environment.

- Variations in phenotypes can be **qualitative** (discrete) or **quantitative** (graduated, continuous). Most quantitative traits result from the effects of several genes and the environment. Genes that together determine quantitative characters are called **quantitative trait loci**.

qualitative Based on observation of an unmeasured quality of a trait, as in brown vs. blue.

quantitative Based on numerical values obtained by measurement, as in quantitative data.

quantitative trait loci A set of genes determining a complex character (trait) that exhibits quantitative variation (variation in amount rather than in kind).

▶ 12.4 Genes Are Carried on Chromosomes

- Each chromosome carries many genes.
- Genes on the same chromosome can recombine by crossing over. The resulting recombinant chromosomes have new combinations of alleles. !!**Review Figures 12.16, 12.17**
- Sex chromosomes are a pair, one of which often determines whether the organism will produce male or female gametes. All other chromosomes are called autosomes. The specific functions of sex chromosomes differ among different groups of organisms.
- Primary sex determination in mammals is usually a function of the presence or absence of the *SRY* gene. **Secondary sex characteristics** are the outward manifestations of maleness and femaleness.

secondary sex characteristics Outward expression of sex determination in organs and tissues, such as body hair and stature in humans.

- In fruit flies and mammals, the X chromosome carries many genes, but the Y chromosome has only a few. Males have only one allele (are **hemizygous**) for X-linked genes, so recessive **sex-linked** mutations are expressed phenotypically more often in males than in females. Females may be unaffected carriers of such alleles. **Review Figure 12.18**

hemizygous (hem' ee zie' gus) [Gk. *hemi*: half + *zygotos*: joined] In a diploid organism, having only one allele for a given trait, typically the case for X-linked genes in male mammals and Z-linked genes in female birds. (Contrast with homozygous, heterozygous.)

sex-linked Gene that is carried on a sex chromosome, such as the X chromosome in mammals.

▶ 12.5 Some Eukaryotic Genes Are Outside the Nucleus

- Cytoplasmic organelles such as plastids and mitochondria contain small numbers of genes. In many organisms, cytoplasmic genes are inherited only from the mother because the male gamete contributes only its nucleus (i.e., no cytoplasm) to the zygote at fertilization. **Review Figure 12.20**

▶ 12.6 Prokaryotes Can Transmit Genes by Mating

- Prokaryotes reproduce primarily asexually but can exchange genes in a sexual process called **bacterial conjugation**. **Review Figure 12.21**

bacterial conjugation See conjugation.

- **Plasmids** are small, extra chromosomes in bacteria that carry genes involved in important metabolic processes and that can be transmitted from one cell to another. **Review Figure 12.22**

plasmid A DNA molecule distinct from the chromosome(s); that is, an extrachromosomal element; found in many bacteria. May replicate independently of the chromosome.

Review

2.4 Genes on the same chromosome are linked.

2.4 Recombinant frequencies can be used to infer gene locations on a chromosome.

Fruit flies (*Drosophila melanogaster*) seem to appear out of nowhere, hovering around bananas, peaches, and other ripe fruit. Biologists, having traced fruit fly origins to West Africa, have hypothesized that expansion of the range of *Drosophila* occurred with human assistance. *Drosophila* can now be found almost everywhere in the world. Though pesky in the kitchen, fruit flies are important laboratory organisms—particularly in genetics research—because of their short life span, ease of care, and many traits that can be observed by simple inspection.

Suppose you were studying fruit flies, looking at easily identified traits encoded by three genes on the same autosomal chromosome. The gene loci are summarized in the figure below. The lowercase letter in each represents the recessive allele; the capital letter represents the dominant allele. The numbers indicate the location in map units of each gene on the chromosome.

Questions

1. Give the genotypes and phenotypes of the F_1 and F_2 generations produced from the cross $DDbb \times ddBB$, assuming no crossing over occurs. Also assume that the F_2 generation is produced by interbreeding the F_1 generation.
2. Give the genotypes and phenotypes of the F_1 and F_2 generations produced from the cross $BBcc \times bbCC$, assuming no crossing over occurs. Also assume that the F_2 generation is produced by interbreeding the F_1 generation.
3. For each of the crosses above, what further phenotypes would appear in the offspring if crossing over occurred? In which cross would you find a higher frequency of recombinants resulting from crossing over? Explain.
1. Draw the chromosomes at the stage where crossing over occurs in meiosis in the $DDbb \times ddBB$ cross in Question 1 above. Show the chromosomes and chromatids before, during, and after crossing over. Clearly label the genes and alleles.

Targeting DNA Replication in Cancer Therapy

Testicular cancer occurs with rapid cell divisions of germ cells and often spreads to other organs. It is the most common cancer in young men and is one of the few tumors of adults that is highly curable, due to a drug called cisplatin.

Dr. Barnett Rosenberg, a scientist at Michigan State University, was curious about how electric fields might affect cells. He put bacteria into a growth medium with platinum electrodes connected to a battery. The result was striking: the bacteria stopped dividing. To generalize the effect of electromagnetism on cells, Rosenberg tried the experiment again, this time using copper and zinc electrodes. (You are probably familiar with the Cu/Zn system if you've taken a chemistry course.) This time the bacteria kept dividing. Only platinum electrodes inhibited cell division.

In light of the data, Rosenberg revised his hypothesis to propose that something leaked out of the platinum electrodes into the medium, and that this “something” blocked cell division. He confirmed his hypothesis by treating bacteria with the medium in which the platinum electrodes had been inserted; the bacteria did not divide. Realizing that cancer cells have uncontrolled cell division, he duplicated his experiments with tumor cells in a laboratory dish. His success at stopping tumor cell growth led to the isolation and development of cisplatin. The drug was so successful with testicular cancer that it has also been used with some success on other tumors. How does it work?

Cisplatin works by making the replication of DNA impossible. As you learned in the last chapter, an essential event for cell division is the complete and precise duplication of the genetic material, DNA. The two strands of DNA unwind and separate, each strand acting as a template for the building of a new strand. Strand separation is possible because the two strands are held together by weak forces, including hydrogen bonds. Cisplatin forms covalent bonds with nucleotides on opposite strands of the DNA, irreversibly cross-linking the two strands together. As a result, the DNA strands cannot separate for replication or expression. With such severe damage to its DNA, the cell then undergoes programmed cell death.

QA What do we need to know about DNA replication to describe the mechanism of a drug that blocks it?

13.1 Experiments Revealed the Function of DNA as Genetic Material

By the early twentieth century, geneticists had associated the presence of genes with chromosomes. Research began to focus on exactly which chemical component of chromosomes composed the genetic material.

focus your learning

Cell staining techniques provided the first pieces of evidence that DNA was the genetic material.

Experiments showed that one strain of bacteria could be genetically transformed to another strain and that DNA was the transforming agent.

Experiments using radiolabeled protein and DNA identified DNA as the material injected by a virus during its infection of a host cell.

Circumstantial evidence indicates that the genetic material is DNA

A hundred years ago, scientists knew that chromosomes were made up of DNA and proteins. At this time a new dye was developed that could bind specifically to DNA and that stained cell nuclei red in direct proportion to the amount of DNA present in the cell. This technique provided circumstantial evidence that DNA was the genetic material:

DNA was in the right place. DNA was confirmed to be an important component of the nucleus and the chromosomes, which were known to carry genes.

DNA was present in the right amounts. The amount of DNA in somatic cells (body cells not specialized for reproduction) was twice that in reproductive cells (eggs or sperm)—as might be expected for diploid and haploid cells, respectively.

DNA varied among species. When cells from different species were stained with the dye and their color intensity measured, each species appeared to have its own specific amount of nuclear DNA.

You should already realize that circumstantial evidence is not a scientific demonstration of cause and effect. After all, proteins are also present in cell nuclei. Science relies on experiments to test hypotheses. The convincing demonstration that DNA is the genetic material came from two sets of experiments, one with bacteria and the other with viruses.

DNA from one type of bacterium genetically transforms another type

In the 1920s, English physician Frederick Griffith was studying the bacterium *Streptococcus pneumoniae*, or pneumococcus, one of the agents that cause pneumonia in humans ([Figure 13.1](#)). He was trying to develop a vaccine against this devastating illness (antibiotics had not yet been discovered). Griffith was working with two strains of pneumococcus:

Figure 13.1 Genetic Transformation

Original Paper: Griffith, F. 1928. The significance of pneumococcal types. *Journal of Hygiene* 27: 113–159.

Griffith's experiments demonstrated that something in the virulent S strain of pneumococcus could transform nonvirulent R strain bacteria into a lethal form, even when the S strain bacteria had been killed by high temperatures.

HYPOTHESIS ▶ Material in dead bacterial cells can genetically transform living bacterial cells.

METHOD

- Cells of the S strain produced colonies that looked smooth (S). Covered by a polysaccharide capsule, these cells were protected from attack by a host's immune system. When S cells were injected into mice, they reproduced and caused pneumonia (the strain was virulent).
- Cells of the R strain produced colonies that looked rough (R), lacked the protective capsule, and were not virulent.

When Griffith injected mice with heat-killed S-type pneumococcus cells, the cells did not produce infection. However, when he injected other mice with a mixture of living R-type cells and heat-killed S-type cells, to his astonishment, the mice died of pneumonia. When he examined blood from these mice, he found it full of living bacteria— many of them with characteristics of the virulent S strain! Griffith concluded that in the presence of the dead S-type pneumococcus cells, some of the living R-type cells had been transformed into virulent S cells. These cells were able to grow and multiply in the mice, causing pneumonia. The fact that these S-type cells reproduced to make more S-type cells showed that the change from R-type to S-type was genetic.

Did this transformation of the bacteria need to occur in the mouse's body? No. The same transformation could be achieved in a test tube by mixing living R cells with heat-killed S cells, or even with a cell-free extract of the heat-killed S-type cells. (A cell-free extract contains all the contents of ruptured cells, but no intact cells.) These results demonstrated that some substance from the dead S pneumococcus cells could cause a heritable change in the living cells.

Oswald Avery and his colleagues at what is now The Rockefeller University identified the substance causing bacterial transformation in two ways:

- Eliminating other possibilities.* Cell-free extracts containing the transforming substance were treated with enzymes that destroyed candidates for the genetic material, such as proteins, RNA, and DNA. When the treated samples were tested, the ones treated with RNase and protease (which destroy RNA and proteins, respectively) were still able to transform R-type bacteria into the S-type. But the transforming activity was lost in the extract treated with

DNase (which destroys DNA) ([Figure 13.2](#)).

Figure 13.2 Genetic Transformation by DNA

Original Paper: Avery, O. T., C. M. MacLeod and M. McCarty. 1944. Studies on the chemical nature of the substance inducing transformation of the pneumococcal types. *Journal of Experimental Medicine* 79: 137–158.

Experiments by Avery and his colleagues showed that DNA from the virulent S strain of pneumococcus was responsible for the transformation in Griffith's experiments (see Figure 13.1).

HYPOTHESIS ▶ The chemical nature of the transforming substance from pneumococcus is DNA.

METHOD

CONCLUSION ▶ Because only DNase destroyed the transforming substance, the transforming substance must be DNA.

- . *Positive experiment.* The researchers isolated virtually pure DNA from a cell-free extract containing the transforming substance. The DNA alone caused bacterial transformation.

We now know that the gene for the enzyme that catalyzes the synthesis of the polysaccharide capsule, which makes the bacterial colony look “smooth,” was transferred into the R cells during transformation.

Viral infection experiments confirmed that DNA is the genetic material

Even with the bacterial transformation experiments, many biologists were still not convinced that DNA is the genetic material. One problem was that DNA, being made up of only four nucleotides (see [Key Concept 4.1](#)), seemed too uniform a substance to be able to confer instructions for all the functions and variety of life. The possibility remained that proteins, with all their chemical and structural diversity (20 amino acids), fulfilled that role. Experiments with a virus were designed to distinguish between these alternatives.

Alfred Hershey and Martha Chase of the Cold Spring Harbor Laboratory in New York studied bacteriophage T2 (phage T2), which infects the bacterium *Escherichia coli*. T2 phage consists of a DNA core packed inside a protein coat ([Figure 13.3](#)). When it attacks a bacterium, part (but not all) of the virus enters the bacterial cell. About 20 minutes later, the cell bursts, releasing dozens of particles that are virtually identical to the infecting virus particle. Clearly the virus is somehow able to hijack the host cell's molecular machinery and convert it into a viral replication machine. Hershey and Chase set out to determine what part of the virus—DNA or protein—enters the host cell to bring about this genetic change. To trace the two components of the virus over its life cycle, the scientists labeled each component with a specific radioisotope:

Figure 13.3 Bacteriophage T2: Reproduction Cycle Bacteriophage T2 is parasitic on *E. coli*, dependent on the bacterium to produce new viruses. The external structures of bacteriophage T2 consist entirely of protein, and the DNA is contained within the protein coat. When the virus infects an *E. coli* cell, its genetic material is injected into the host bacterium.

Proteins were labeled with radioactive sulfur. Proteins contain some sulfur (in the amino acids cysteine and methionine), but DNA does not. Sulfur has a radioactive isotope, ^{35}S . Hershey and Chase grew bacteriophage T2 in a bacterial culture in the presence of ^{35}S , so the proteins of the resulting viruses were labeled with (contained) the radioisotope.

DNA was labeled with radioactive phosphorus. DNA contains a lot of phosphorus (in the deoxyribose-phosphate backbone—see [Figure 4.4](#)), whereas proteins contain little or none. Phosphorus also has a radioisotope, ^{32}P . The researchers grew another batch of T2 in a bacterial culture in the presence of ^{32}P , thus labeling the viral DNA with ^{32}P .

Hershey and Chase used these radioactively labeled viruses in their experiments ([Figure 13.4](#)). In one experiment, they allowed ^{32}P -labeled bacteriophage to infect bacteria; in the other, the

bacteria were infected with ^{35}S -labeled bacteriophage. After a few minutes they agitated each mixture vigorously in a kitchen blender, stripping away the parts of the viruses that had not penetrated the bacteria, without bursting the bacteria. Then they separated the bacteria from the rest of the material (the remains of the viruses) from each experiment individually in a centrifuge. The result was that the bacterial cells in the centrifuge pellet contained most of the ^{32}P (and thus the viral DNA), and the supernatant fluid with the viral remains contained most of the ^{35}S (and thus the viral protein). These results indicated that it was the DNA that had been transferred into the bacteria, and that DNA was the molecule responsible for redirecting the genetic program of the bacterial cell.

experiment

[Figure 13.4](#) The Hershey–Chase Experiment

Original Paper: Hershey, A. D. and M. Chase. 1952. Independent functions of viral protein and nucleic acid in growth of bacteriophage. *The Journal of General Physiology* 36: 39–56.

When Hershey and Chase infected bacterial cells with radioactively labeled T2 bacteriophage, only labeled DNA was found in the bacteria. The infected cells were agitated to remove the viral coats from the bacteria and were then centrifuged to pellet the bacteria. The labeled protein remained in the supernatant. This showed that DNA, not protein, is the genetic material.

HYPOTHESIS ► Either component of a bacteriophage—DNA or protein—might be the hereditary material that enters a bacterial cell to direct the assembly of new viruses.

METHOD

1a Label phage. P is an element in DNA, but not in proteins.

1b Label phage. S is an element in proteins, but not in DNA.

CONCLUSION ▶ DNA, not protein, enters bacterial cells and directs the assembly of new viruses.

A work with the data exercise that accompanies this figure may be assigned in LaunchPad

Eukaryotic cells can also be genetically transformed by DNA

The transformation of eukaryotic cells by DNA is often called **transfection**. This can be demonstrated using a **genetic marker**, a gene whose presence in the recipient cells confers an observable phenotype. When transforming both prokaryotes and eukaryotes, researchers often use a genetically determined selection marker, for example, antibiotic resistance or a nutritional requirement, which permits the growth of transformed cells but not of nontransformed cells. A common marker in mammalian transfection experiments is a gene that confers resistance to the antibiotic neomycin. Transfection is achieved by various methods, including chemical treatments that allow the DNA to be taken up by the cells. Any cell can be transfected, even an egg cell. In the latter case, a whole new genetically transformed organism can result, known as a **transgenic organism**. Transformation in eukaryotes offers conclusive evidence that DNA is the genetic material.

transfection Insertion of recombinant DNA into animal cells.

genetic marker (1) In gene cloning, a gene of identifiable phenotype that indicates the presence of another gene, DNA segment, or chromosome fragment. (2) In general, a DNA sequence such as a single nucleotide polymorphism whose presence is correlated with the presence of other linked genes on that chromosome.

13.1 recap

Experiments on bacteria and on viruses demonstrated that DNA is the genetic material. DNA from one genetic strain of bacteria was able to genetically transform another strain into the donor strain. Viral DNA was shown to be injected into a host cell and to genetically change that cell into a virus factory.

learning outcomes

You should be able to:

- Describe evidence from cell staining techniques that DNA was the genetic material.
- Explain how experiments conducted by Griffith and Avery provided evidence that DNA was the genetic material.
- Justify the experimental design used by Hershey and Chase.
- Design an experiment to test the hypothesis that DNA and not protein is the cellular material that carries genetic information.

1. At the time of Griffith's experiments in the 1920s, what circumstantial evidence suggested to scientists that DNA might be the genetic material?
2. How did the experiments of Avery and his colleagues rule out protein as the genetic material?
3. What attributes of bacteriophage T2 were key to the Hershey–Chase experiments demonstrating that DNA, rather than protein, is the genetic material?
4. Outline a series of experiments using radioactive isotopes (such as ^{32}P and ^{35}S) to show that it is DNA and not protein that moves from the donor cell to the recipient cell and is responsible for bacterial transformation.

The transformation and viral infection experiments convinced biologists that the genetic material is DNA. It had been known for several decades that chemically, DNA is a polymer of nucleotides. Next, scientists turned to DNA's precise three-dimensional structure.

13.2 DNA Has a Structure That Suits Its Function

In determining the structure of DNA, scientists hoped to answer two questions: (1) how is DNA replicated between cell divisions, and (2) how does it direct the synthesis of specific proteins? DNA's structure was deciphered only after many types of experimental evidence were considered together in a theoretical framework.

focus your learning

Watson and Crick used X-ray diffraction data in conjunction with chemical evidence to build the double helix model for DNA.

The genetic material performs four important functions and is well suited to its biological functions

How did Watson and Crick deduce the structure of DNA?

Once pure DNA fibers could be isolated, biophysicists and biochemists examined the DNA for hints about its structure. The evidence eventually used to solve DNA's structure included crucial data obtained using X-ray crystallography and a thorough characterization of the chemical composition of DNA.

PHYSICAL EVIDENCE FROM X-RAY DIFFRACTION

Some chemical substances, when they are isolated and purified, can be made to form crystals. The positions of atoms in a crystallized substance can be inferred from the diffraction pattern of X rays passing through the substance. In the early 1950s the New Zealand-born biophysicist Maurice Wilkins discovered a way to make highly ordered fibers of DNA that were suitable for X-ray diffraction studies. His samples were analyzed by Rosalind Franklin of Kings College, London ([Figure 13.5](#)). Franklin's data suggested that DNA was a double (two-stranded) helix with ten nucleotides in each full turn, and that each full turn was 3.4 nanometers (nm) in length. The molecule's diameter of 2 nm suggested that the sugar-phosphate backbone of each DNA strand must be on the outside of the helix.

Figure 13.5 X-Ray Diffraction Helped Reveal the Structure of DNA (A) The positions of atoms in a crystallized chemical substance can be inferred by the pattern of diffraction of X rays passed through it. The pattern of DNA is both highly regular and repetitive. (B) Rosalind Franklin's diffraction and her "photograph 51" (shown)

helped scientists visualize the helical structure of the DNA molecule.

CHEMICAL EVIDENCE FROM BASE COMPOSITION

Biochemists knew that DNA was a polymer of nucleotides. Each nucleotide consists of a molecule of the sugar deoxyribose, a phosphate group, and a nitrogen-containing base (see [Figure 4.1](#)). The only differences among the four nucleotides of DNA are their nitrogenous bases: the purines **adenine (A)** and **guanine (G)**, and the pyrimidines **cytosine (C)** and **thymine (T)**.

adenine (A) (a' den een) A nitrogen-containing base found in nucleic acids, ATP, NAD, and other compounds.

guanine (G) (gwan' een) A nitrogen-containing base found in DNA, RNA, and GTP.

cytosine (C) (site' oh seen) A nitrogen-containing base found in DNA and RNA.

thymine (T) Nitrogen-containing base found in DNA.

In the early 1950s, biochemist Erwin Chargaff and his colleagues at Columbia University reported that DNA from many different species—and from different sources within a single organism—exhibits certain regularities. This led to the following rule: In any DNA sample, the amount of adenine equals the amount of thymine ($A = T$), and the amount of guanine equals the amount of cytosine ($G = C$). As a result, the total abundance of purines ($A + G$) equals the total abundance of pyrimidines ($T + C$):

Chargaff's rule provided an important clue about the way the bases are arranged in a DNA double helix. While Chargaff and colleagues found that this rule held for every organism they examined, they noted that the relative abundances of $A + T$ versus $G + C$ vary among organisms. In human DNA, A and T each account for 30 percent of the nitrogenous bases present, while G and C each account for 20 percent. Put another way, in human DNA there is a ratio of 60 percent ($A + T$) to 40 percent ($C + G$).

WATSON AND CRICK'S MODEL

If you have taken chemistry courses, you may be familiar with model building, where balls (atoms) and sticks (bonds) are used to put together molecules based on known physical and chemical properties and bond angles. A physicist, Francis Crick, and a geneticist, James D. Watson ([Figure 13.6A](#)), who were then at the Cavendish Laboratory of Cambridge University, used model building to solve the structure of DNA. They used the physical and chemical evidence we just described:

(A)

(B)

The blue bands represent the two sugar-phosphate backbones, which run in opposite directions:

Figure 13.6 DNA Is a Double Helix (A) James Watson (left) and Francis Crick (right) proposed that the DNA molecule has a double-helical structure. (B) Biochemists can now pinpoint the position of every atom in a DNA molecule. To see that the essential features of the original Watson–Crick model have been verified, follow with your eyes the double-helical chains of sugar–phosphate groups and note the horizontal rungs of the bases.

In DNA, where do the following chemical forces occur: hydrogen bonds, covalent bonds, and van der Waals forces?

 Media Clip 13.1 Discovery of the Double Helix www.Life11e.com/mc13.1

To be consistent with Franklin's X-ray diffraction images, Watson and Crick's model had the nucleotide bases on the interior of the two strands, with a sugar-phosphate "backbone" on the outside. In addition, the two DNA strands ran in opposite directions, that is, they were **antiparallel**. The two strands would not fit together otherwise:

antiparallel Pertaining to molecular orientation in which a molecule or parts of a molecule have opposing directions.

To satisfy Chargaff's rule ($A = T$ and $G = C$), Watson and Crick's model always paired a purine on one strand with a pyrimidine on the opposite strand. These **base pairs** (A-T and G-C) have the same width down the double helix, a uniformity that was also confirmed by X-ray diffraction:

base pair (bp) In double-stranded DNA, a pair of nucleotides formed by the complementary base pairing of a purine on one strand and a pyrimidine on the other. (See complementary base pairing.)

Crick and Watson built their tin model of DNA in late February 1953. This structure explained the known chemical properties of DNA, and it opened the door to understanding its biological functions.

Four key features define DNA structure

Four features summarize the molecular architecture of the DNA molecule (**Figure 13.6B**):

- DNA is a *double-stranded helix*, with a sugar–phosphate backbone on the outside and base pairs lined up on the inside.
- DNA is usually a *right-handed helix*. If you curl the fingers of your right hand and point your thumb upward, the curve of the helix follows the direction of your fingers, and it winds upward in the direction of your thumb. (See [Figure 3.8](#), of right- versus left-handed helices.)
- DNA is *antiparallel* (the two strands run in opposite directions).
- DNA has *major and minor grooves* in which the outer edges of the nitrogenous bases are exposed.

THE HELIX

The sugar–phosphate backbones of the polynucleotide chains form a coil around the outside of the helix, and the nitrogenous bases point toward the center. The chains are held together by two chemical forces:

- *Hydrogen bonding* between specifically paired bases. Consistent with Chargaff's rule, adenine (A) pairs with thymine (T) by forming two hydrogen bonds, and guanine (G) pairs with cytosine (C) by forming three hydrogen bonds:

Every base pair consists of one purine (A or G) and one pyrimidine (T or C). This pattern is known as [complementary base pairing](#).

complementary base pairing The AT (or AU), TA (or UA), CG, and GC pairing of bases in double-stranded DNA, in transcription, and between tRNA and mRNA.

- *van der Waals* forces between adjacent bases on the same strand. When the base rings come near one another, they tend to stack like poker chips because of these weak attractions.

ANTIPARALLEL STRANDS

The backbone of each DNA strand contains repeating units of the five-carbon monosaccharide deoxyribose:

The number followed by a prime (') designates the position of a carbon atom in this sugar molecule. In the sugar–phosphate backbone of DNA, the phosphate groups are connected to the 3' carbon of one deoxyribose molecule and the 5' carbon of the next, linking successive sugars together.

Thus the two ends of a polynucleotide chain differ. At one end of a chain is a free (not connected to another nucleotide) 5' phosphate group (—OPO_3^-); this is called the **5' end**. At the other end is a free 3' hydroxyl group (—OH); this is called the **3' end**. In a DNA double helix, the 5' end of one strand is paired with the 3' end of the other strand, and vice versa. In other words, if you drew an arrow for each strand running from 5' to 3', the arrows would point in opposite directions (see also [Figure 4.4A](#)).

5' end The end of a DNA or RNA strand that has a free phosphate group at the 5' carbon of the sugar (deoxyribose or ribose).

3' end (3 prime) The end of a DNA or RNA strand that has a free hydroxyl group at the 3' carbon of the sugar (deoxyribose or ribose).

BASE EXPOSURE IN THE GROOVES

Look back at [Figure 13.6B](#) and note the major and minor grooves in the helix. These grooves exist because the backbones of the two strands are closer together on one side of the double helix (forming the minor groove) than on the other side (forming the major groove). [Figure 13.7](#) shows a “top-down” view of the four possible configurations of the flat, hydrogen-bonded base pairs in the major and minor grooves. The exposed outer edges of the base pairs are accessible for additional hydrogen bonding. Note that the arrangements of unpaired atoms and groups differ in A-T and G-C pairs. Thus, the *surfaces of the A-T and C-G base pairs are chemically distinct*, allowing other molecules such as proteins to recognize specific base pair sequences and bind to them, which is crucial for DNA function. *The binding of proteins to specific base pair sequences is the key to protein–DNA interactions*, which are necessary for the replication and expression of the genetic information in DNA.

Figure 13.7 Base Pairs in DNA Can Interact with Other Molecules These diagrams show the four possible configurations of base pairs within the double helix. Atoms shaded in green are available for hydrogen bonding with other molecules, such as proteins.

The double-helical structure of DNA is essential to its function

The genetic material performs four important functions, and the DNA structure proposed by Watson and Crick was elegantly suited to three of them.

- *The genetic material stores an organism's genetic information.* With its millions of nucleotides, the base sequence of a DNA molecule can encode and store an enormous amount of information. Variations in DNA sequences can account for species and individual differences. DNA fits this role nicely.
- *The genetic material is susceptible to mutations (permanent changes) in the information it encodes.* For DNA, mutations might be simple changes in the linear sequence of base pairs.
- *The genetic material is precisely replicated in the cell division cycle.* Replication could be accomplished by complementary base pairing, A with T and G with C. In the original publication of their findings in 1953, Watson and Crick coyly pointed out, "It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material."
- *The genetic material (the coded information in DNA) is expressed as the phenotype.* This function is not obvious in the structure of DNA. However, as we will see in the next chapter, the nucleotide sequence of DNA is copied into RNA, which uses the coded information to specify a linear sequence of amino acids—a protein. The folded forms of proteins determine many of the phenotypes of an organism.

13.2 recap

DNA is a double helix made up of two antiparallel polynucleotide chains. The two chains are joined by hydrogen bonds between the nucleotide bases, which pair specifically: A with T, and G with C. Chemical groups on the bases that are exposed in the grooves of the helix are available for hydrogen bonding with other molecules, such as proteins. Various molecules that interact with DNA can recognize specific sequences of nucleotide bases because the surfaces of the base pairs are chemically distinct.

learning outcomes

You should be able to:

- Explain how Watson and Crick developed their model of DNA.
 - Relate structural aspects of the DNA molecule to its biological functions.
-
1. Describe the evidence that Watson and Crick used to come up with the double helix model for DNA.
 2. How does the two-stranded structure of DNA relate to its functions?
 3. A key to the function of DNA in directing information in the cell is the binding of other molecules such as proteins to the double helix at specific base sequences. Recalling the forces involved in protein interactions (see [Figure 3.12](#)) and the chemical groupings

exposed in base pairs (see [Figure 13.7](#)), how do specific interactions between proteins and DNA occur?

Once the structure of DNA was understood, it was possible to investigate how DNA replicates itself. Next we will examine the experiments that taught us how this elegant process works.

13.3 DNA Is Replicated Semiconservatively

The mechanism of DNA replication that Watson and Crick proposed was soon confirmed. First, researchers showed that DNA could be replicated in a test tube containing simple substrates and an enzyme. A subsequent study showed that each of the two strands of the double helix can serve as a template for a new strand of DNA.

focus your learning

The Meselson-Stahl experiment provided evidence to support the semiconservative model of DNA replication

Semiconservative DNA replication requires deoxyribonucleoside triphosphates, DNA polymerase, and a DNA template.

DNA replication proceeds bidirectionally from an origin of replication (*ori*); *E. coli* has a single *ori*, and eukaryotic chromosomes have multiple ones.

The first replication event at the *ori* uses DNA helicases and single-stranded binding proteins.

Test tube synthesis of DNA needed the following substances:

The deoxyribonucleoside triphosphates dATP, dCTP, dGTP, and dTTP. These are the monomers from which the DNA polymers are formed.

DNA molecules of a particular sequence that serve as **templates** to direct the sequence of nucleotides in the new molecules.

A **DNA polymerase** enzyme to catalyze the polymerization reaction.

Salts and a pH buffer, to create an appropriate chemical environment for the DNA polymerase.

template A molecule or surface on which another molecule is synthesized in complementary fashion, as in the replication of DNA.

DNA polymerase Any of a group of enzymes that catalyze the formation of DNA strands from a DNA template.

The fact that DNA could be synthesized in a test tube confirmed that a DNA molecule contains the information needed for its own replication. The next challenge was to determine which of three possible replication patterns occurs during DNA replication:

- *Semiconservative replication*, in which each parent strand serves as a template for a new strand, and the two new DNA molecules each have one old and one new strand ([Figure 13.8A](#))
- *Conservative replication*, in which the original double helix serves as a template for, but does not contribute to, a new double helix ([Figure 13.8B](#))
- *Dispersive replication*, in which fragments of the original DNA molecule serve as templates for assembling two new molecules, each containing old and new parts, perhaps at random ([Figure 13.8C](#))

Figure 13.8 Three Models for DNA Replication In each model, the original DNA is shown in blue and the newly synthesized DNA is in red.

Watson and Crick's original paper suggested that DNA replication was semiconservative, but the test tube demonstration described above did not provide a basis for choosing among these three models.

 **Animation 13.2 DNA Replication and Polymerization** www.Life11e.com/a13.2

An elegant experiment demonstrated that DNA replication is semiconservative

In 1958 Matthew Meselson and Franklin Stahl at the California Institute of Technology convinced the scientific community that DNA is reproduced by **semiconservative replication**. They used density labeling to distinguish between parent strands of DNA and newly copied ones. Historians of science have called this one of the “most beautiful experiments” in biology. For that reason alone, as well as its results, it's worth taking a close look at it.

semiconservative replication The way in which DNA is synthesized. Each of the two partner strands in a double helix acts as a template for a new partner strand. Hence, after replication, each double helix consists of one old and one new strand.

The key to the experiment was the use of a “heavy” isotope of nitrogen. Heavy nitrogen (^{15}N) is a rare, nonradioactive isotope that makes molecules containing it denser than chemically identical molecules containing the common isotope ^{14}N . Two cultures of the bacterium *E. coli* were grown for many generations, one in a medium containing ^{15}N and the other in a medium containing ^{14}N . When DNA extracts from the two cultures were combined and centrifuged in a solution of cesium chloride, which forms a density gradient under centrifugation, two separate bands of DNA formed in the centrifugation tube. The DNA from the ^{15}N culture was heavier than the DNA from the ^{14}N culture, so it formed a band at a different position in the density gradient.

[Figure A](#) in the work with the data portion of **Investigating Life: The Meselson–Stahl Experiment** shows a photo of the two bands.

Next, Meselson and Stahl grew another *E. coli* culture in ^{15}N medium, then transferred the bacteria to normal ^{14}N medium and allowed them to continue growing. The cells replicated their DNA and divided every 20 minutes. Meselson and Stahl collected some of the bacteria at time intervals and extracted DNA from the samples. You can follow their results for the first two generations in Investigating Life: The Meselson–Stahl Experiment. The results can be explained only by the semiconservative model of DNA replication. The crucial observations demonstrating this model were that all the DNA at the end of the first generation was of intermediate density, while at the end of the second generation there were two discrete bands: one of intermediate and one of light DNA. If the conservative model had been true, there would have been no intermediate density DNA. If the dispersive model were correct, then the DNA would all have been intermediate for the first few generations, with the single intermediate band becoming progressively lighter.

Animation 13.3 The Meselson–Stahl Experiment www.Life11e.com/a13.3

Not long after this experiment, other scientists investigated DNA replication in the presence of cisplatin (described in the opening story of this chapter). Repeating the Meselson–Stahl experiment with cisplatin added to the growth media, they found no change in the density of DNA after several generations—that is, only one DNA band formed in the tubes subjected to centrifugation. From this the researchers deduced that in the presence of cisplatin the two strands of DNA must not be separating during replication. We will discuss more specifically how cisplatin prevents DNA strand separation at the end of this chapter. First, let's consider the chemistry involved in DNA replication.

There are two steps in DNA replication

Semiconservative DNA replication in the cell involves several different enzymes and other proteins. It takes place in two general steps:

- . The DNA double helix is unwound to separate the two template strands and make them available for new base pairing.
- . As new nucleotides form complementary base pairs with template DNA, they are covalently linked together by phosphodiester bonds, forming a polymer whose base sequence is complementary to the bases in the template strand.

The nucleotides that make up DNA are deoxyribonucleoside monophosphates because they each contain deoxyribose and one phosphate group (see [Figure 4.1](#)). The four free monomers that are brought together to form DNA are the deoxyribonucleoside triphosphates dATP, dTTP, dCTP, and dGTP, collectively referred to as dNTPs. They are called triphosphates because each has three phosphate groups. The three phosphate groups are attached to the 5' carbon on the deoxyribose sugar (as shown in the incoming nucleotide in [Figure 13.9](#)).

investigatinglife

Experiment

The Meselson–Stahl

experiment

Original Paper: Meselson, M. and F. Stahl. 1958. The replication of DNA in *Escherichia coli*. *Proceedings of the National Academy of Sciences USA* 44: 671–682.

A centrifuge was used to separate DNA molecules labeled with isotopes of different densities. This experiment revealed a pattern that supports the semiconservative model of DNA replication.

HYPOTHESIS ▶ DNA replicates semiconservatively.

METHOD

1 Grow bacteria in ^{15}N (heavy) medium.

2 Transfer some bacteria to ^{14}N (light) medium; bacterial growth continues.

4 Extract DNA from bacteria. Put DNA into a solution.

3 Samples are taken after 0 minutes, 20 minutes (after one round of replication), and 40 minutes (two rounds of replication).

RESULTS

$^{14}\text{N}/^{14}\text{N}$ (light) DNA

$^{14}\text{N}/^{15}\text{N}$ (intermediate) DNA

$^{15}\text{N}/^{15}\text{N}$ (heavy) DNA

Parent
(all heavy)

First
generation
(all intermediate)

Second
generation
(half intermediate,
half light)

INTERPRETATION

Before the bacteria reproduce for the first time in the light medium (at 0 minutes), all DNA (parental) is heavy.

Parent strand ^{15}N New strand ^{14}N

After two generations, half the DNA is intermediate and half is light; there was no heavy DNA.

CONCLUSION ▶ This pattern could only have been observed if each DNA molecule contains a template strand from the parental DNA; thus DNA replication is semiconservative.

work with the data

The Meselson–Stahl experiment has been called one of the “most beautiful experiments” in biology because of its essential simplicity. Meselson and Stahl used density gradients to examine how DNA molecules replicate, as illustrated in the experimental results shown in **Figure A**. The peaks on the drawing are proportional to the amount of DNA.

Figure B shows results of the experiment after each of four generations. Each sample contained the same number of bacteria, so the total amount of DNA in each panel was the same.

QUESTIONS

1. Use the heights of the peaks to estimate the percent of total DNA that was heavy, intermediate, and light at each generational stage. Create a table summarizing these calculations and discuss whether they support the authors' conclusions.
2. What would the data look like if the bacteria had been allowed to divide for three more generations?
3. If Meselson and Stahl had done their experiment starting with light DNA and then added ¹⁵N for succeeding generations, what would the bands look like?
4. What would the data look like if conservative replication were the correct model? What would the data look like if dispersive replication were correct?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

ORIGINS OF REPLICATION

The single circular chromosome of the bacterium *E. coli* has 4×10^6 base pairs (bp) of DNA. The 245 bp *ori* sequence is at a particular location on the chromosome. Once the pre-replication complex binds to it, the DNA is unwound and replication proceeds in both directions around the circle, forming two **replication forks** (**Figure 13.10A**). The replication rate in *E. coli* is approximately 1,000 bp per second, so it takes about 40 minutes to fully replicate the chromosome (with two replication forks). Rapidly dividing *E. coli* cells divide every 20 minutes. In these cells, new rounds of replication begin at the *ori* of each new chromosome before the first chromosome has fully replicated. In this way the cells can divide more frequently than the time needed to finish replicating the original chromosome.

replication fork A point at which a DNA molecule is replicating. The fork forms by the unwinding of the parent molecule.

(A) A single *ori* in a prokaryotic chromosome

(B) Multiple ori in a eukaryotic chromosome

Figure 13.10 The Origin of DNA Replication (A) Prokaryotic chromosomes usually have a single origin where DNA replication starts and proceeds in both directions. (B) The usually much larger eukaryotic chromosome typically has multiple replication origins.

Eukaryotic chromosomes are typically much longer than those of prokaryotes—up to 1 billion bp—and are linear, not circular. If replication occurred from a single *ori* with two forks growing away from each other, it would take weeks to fully replicate a chromosome. So eukaryotic chromosomes have multiple origins of replication, scattered at intervals of 10,000 to 40,000 bp ([Figure 13.10B](#)).

DNA REPLICATION BEGINS WITH A PRIMER

A DNA polymerase elongates a polynucleotide strand by covalently linking new nucleotides to a preexisting strand. However, it cannot start this process without a short “starter” strand, called a [primer](#). In most organisms this primer is a short single strand of RNA ([Figure 13.11](#)), but in some organisms it is DNA. The primer is complementary to the DNA template and is synthesized one nucleotide at a time by an enzyme called a [primase](#). The DNA polymerase then adds nucleotides to the 3' end of the primer and continues until the replication of that section of DNA has been completed. Then the RNA primer is degraded, DNA is added in its place, and the resulting DNA fragments are connected by the action of other enzymes. When DNA replication is complete, each new strand consists only of DNA.

primer Strand of nucleic acid, usually RNA, that is the necessary starting material for the synthesis of a new DNA strand, which is synthesized from the 3' end of the primer.

primase (prigh' maze) An enzyme that catalyzes the synthesis of a primer for DNA replication.

Figure 13.11 DNA Forms with a Primer DNA polymerases require a primer—a “starter” strand of DNA or RNA to which they can add new nucleotides.

DNA POLYMERASES ARE LARGE

DNA polymerases are much larger than their substrates (the dNTPs) and the template DNA, which is very thin. Molecular models of the enzyme-substrate-template complex from bacteria show that the enzyme is shaped like an open right hand with a palm, a thumb, and fingers ([Figure 13.12](#)). Within the “palm” is the active site of the enzyme, which brings together each dNTP substrate and the template. The “finger” regions have precise shapes that can recognize the different shapes of the four nucleotide bases. They bind to the bases by hydrogen bonding and rotate inward. Most cells contain more than one kind of DNA polymerase, but only one of them is responsible for chromosomal DNA replication. The others are involved in primer removal and DNA repair. Fifteen DNA polymerases have been identified in humans, whereas the bacterium *E. coli* has five DNA polymerases.

Figure 13.12 DNA Polymerase Binds to the Template Strand (A) The DNA polymerase enzyme (tan) is much larger than the DNA molecule (red and blue). (B) DNA polymerase is shaped like a hand, and in this side-on view, its “fingers” can be seen curling around the DNA. These “fingers” can recognize the distinctive shapes of the four bases.

Many other proteins assist with DNA polymerization

Various other proteins play roles in other replication tasks; some of these are shown in **Focus: Key Figure 13.13**. The first event at the origin of replication is the localized unwinding and separation (denaturation) of the DNA strands. As we discussed in [Key Concept 13.2](#), the two strands are held together by hydrogen bonds and van der Waals forces. An enzyme called **DNA helicase** uses energy from ATP hydrolysis to unwind and separate the strands, and **single-strand binding proteins** bind to the unwound strands to keep them from reassociating into a double helix. This process makes each of the two template strands available for complementary base pairing.

focus: key figure

Figure 13.13 Many Proteins Collaborate in the Replication Complex Several proteins in addition to DNA polymerase are involved in DNA replication. The two molecules of DNA polymerase shown here are actually part of the same complex.

Q: In bidirectional replication from a single origin point, with two replication forks moving in

opposite directions, will the same DNA strands be leading and lagging?

Activity 13.1 The Replication Complex www.Life11e.com/ac13.1

DNA helicase An enzyme that unwinds the double helix.

single-strand binding protein In DNA replication, a protein that binds to single strands of DNA after they have been separated from each other, keeping the two strands separate for replication.

The two DNA strands grow differently at the replication fork

The DNA at the replication fork—the site where DNA unwinds to expose the bases so that they can act as templates—opens up like a zipper in one direction. Study [Figure 13.14](#) and try to imagine what is happening over a short period of time. Remember that the two DNA strands are antiparallel; that is, the 3' end of one strand is paired with the 5' end of the other.

Figure 13.14 The Two New Strands Form in Different Ways As the parent DNA unwinds, both new strands are synthesized in the 5'-to-3' direction, although their template strands are antiparallel. The leading strand grows continuously forward, but the lagging strand grows in short discontinuous stretches called Okazaki fragments. Eukaryotic Okazaki fragments are hundreds of nucleotides long, with gaps between them.

Animation 13.4 Leading and Lagging Strand Synthesis www.Life11e.com/a13.4

One newly replicating strand (the **leading strand**) is oriented so that it can grow continuously at its 3' end as the fork opens up.

The other new strand (the **lagging strand**) is oriented so that as the fork opens up, its exposed 3' end gets farther and farther away from the fork, and an unreplicated gap is formed. This gap would get bigger and bigger if there were not a special mechanism to overcome this problem.

leading strand In DNA replication, the daughter strand that is synthesized continuously. (Contrast with lagging strand.)

lagging strand In DNA replication, the daughter strand that is synthesized in discontinuous stretches. (See Okazaki fragments. Contrast with leading strand.)

Synthesis of the lagging strand requires the synthesis of relatively small, discontinuous stretches of DNA (100–200 nucleotides in eukaryotes; 1,000–2,000 nucleotides in prokaryotes). These discontinuous stretches are synthesized just as the leading strand is, by the addition of new nucleotides one at a time to the 3' end of the new strand, but the synthesis of this new strand moves in the direction opposite to that in which the replication fork is moving. These stretches of new DNA are called **Okazaki fragments** (after their discoverer, the Japanese biochemist Reiji Okazaki). While the leading strand grows continuously “forward,” the lagging strand grows in shorter, “backward” stretches with gaps between them.

Okazaki fragments Newly formed DNA making up the lagging strand in DNA replication. DNA ligase links Okazaki fragments together to give a continuous strand.

A single primer is needed for synthesis of the leading strand, but each Okazaki fragment requires its own primer to be synthesized by the primase. In bacteria, DNA polymerase III then synthesizes an Okazaki fragment by adding nucleotides to one primer until it reaches the primer of the previous fragment (**Figure 13.15**). At this point, DNA polymerase I removes the old primer and replaces it with DNA. Left behind is a tiny nick—the final phosphodiester linkage between the adjacent Okazaki fragments is missing. The enzyme **DNA ligase** catalyzes the formation of that bond, linking the fragments and making the lagging strand whole.

Figure 13.15 The Lagging Strand Story In bacteria, DNA polymerase I and DNA ligase cooperate with DNA polymerase III to complete the complex task of synthesizing the lagging strand.

DNA ligase Enzyme that unites broken DNA strands during replication and recombination.

DNA replication involves remarkable teamwork among various proteins that act on the DNA strands. Let's review the proteins involved in DNA replication in the order of their activity at the replication fork:

DNA helicase unwinds the double helix and separates the two strands.

Single-strand binding proteins bind to separated strands and prevent them from re-forming the double helix.

DNA primase makes RNA primers.

DNA polymerase links new nucleotides to form the new DNA strands and removes the primers.

DNA ligase connects Okazaki fragments made by DNA polymerase to one another.

Working together, these proteins make new DNA at a rate in excess of 1,000 base pairs per second, committing errors in fewer than 1 base in a million.

A SLIDING CLAMP INCREASES THE RATE OF DNA REPLICATION

How do DNA polymerases work so fast? We saw in [Key Concept 8.3](#) that an enzyme catalyzes a chemical reaction:

Substrate binds to enzyme → *one* product is formed → enzyme is released → cycle repeats

DNA replication would not proceed as rapidly as it does if it went through such a cycle for each nucleotide. Instead, DNA polymerases are **processive**—that is, they catalyze the formation of many phosphodiester linkages each time they bind to a DNA molecule:

processive Pertaining to an enzyme that catalyzes many reactions each time it binds to a substrate, as DNA polymerase does during DNA replication.

Substrates bind to enzyme → *many* products are formed → enzyme is released → cycle repeats

The DNA polymerase–DNA complex is stabilized by a **sliding DNA clamp**, which has multiple identical subunits assembled into a doughnut shape ([Figure 13.16](#)). The doughnut's "hole" is just large enough to encircle the DNA double helix, along with a thin layer of water molecules for lubrication. The clamp binds to the DNA polymerase–DNA complex, keeping the enzyme and the DNA associated tightly with each other. If the clamp is absent, DNA polymerase dissociates from DNA after forming 20 to 100 phosphodiester linkages. With the clamp, it can polymerize up to 50,000 nucleotides before it detaches.

sliding DNA clamp Protein complex that keeps DNA polymerase bound to DNA during replication.

Figure 13.16 A Sliding DNA Clamp Increases the Efficiency of DNA

Polymerization The clamp increases the efficiency of polymerization by keeping the enzyme bound to the substrate, so the enzyme does not have to repeatedly bind to template and substrate.

DNA IS THREADED THROUGH A REPLICATION COMPLEX

So far, you are probably envisioning DNA replication as a locomotive (the replication complex) moving along a railroad track (the DNA). But this is not so. Commonly in eukaryotes, the replication complexes seem to be stationary, attached at specific positions in the nucleus. It is the DNA that moves, essentially sliding into the replication complex as one double-stranded molecule and emerging as two double-stranded molecules.

Telomeres are not fully replicated and are prone to repair

As we will discuss in [Key Concept 13.4](#), DNA may be damaged by radiation or chemicals. When this happens, DNA repair mechanisms are activated, and breaks exposing free 3' and 5' groups

in DNA are rejoined via a combination of DNA synthesis and DNA ligase activity. So the ends of chromosomes are a potential problem: the DNA repair system might recognize the ends as breaks, and join two chromosomes together. This would create havoc with genomic integrity.

In many eukaryotes, there are repetitive sequences at the ends of chromosomes called **telomeres**. In humans, the telomere sequence is TTAGGG-3', and it is repeated about 2,500 times at each chromosome end. These repeats bind special proteins that prevent the DNA repair system from recognizing the chromosome ends as breaks. In addition, the repeats may form loops that have a similar protective role.

telomeres (tee' lo merz) [Gk. <i>telos</i>: end + <i>meros</i>: units, segments] Repeated DNA sequences at the ends of eukaryotic chromosomes.
--

But there is another problem with chromosome ends. As you have seen, replication of the lagging strand occurs by the addition of Okazaki fragments to RNA primers. When the terminal RNA primer is removed, no DNA can be synthesized to replace it because there is no 3' end to extend. In most cells, the short piece of single-stranded DNA at each end of the chromosome is removed. Thus the chromosome becomes slightly shorter with each cell division (**Figure 13.17**).

Figure 13.17 Telomeres and Telomerase (A) In most cells, the chromosome shortens with each replication because the nonreplicated DNA at the 3' end of the template DNA is removed. However, in stem cells telomerase uses an RNA template to extend the telomere and prevent chromosome shortening. (B) Bright fluorescent staining marks the telomeric regions on these blue-stained human chromosomes.

Q: Why do the cells that form gametes express telomerase?

Each human chromosome can lose 50 to 200 base pairs of telomeric DNA after each round of DNA replication and cell division. After many cell divisions, the genes near the ends of the chromosomes can be lost, and the cell dies. This phenomenon explains, in part, why many cell lineages do not last the entire lifetime of the organism: their telomeres are lost. Continuously dividing cells, such as bone marrow stem cells and gamete-producing cells, have a special mechanism for maintaining their telomeric DNA. An enzyme called **telomerase** catalyzes the addition of any lost telomeric sequences in these cells (see [Figure 13.18](#)). Telomerase contains an RNA sequence that acts as a template for the telomeric DNA repeat sequence.

telomerase An enzyme that catalyzes the addition of telomeric sequences lost from chromosomes during DNA replication.

Figure 13.18 DNA Repair Mechanisms The proteins of the replication complex function in DNA repair mechanisms, reducing the rate of errors in the replicated DNA. Another mechanism (excision repair) repairs damage to existing DNA molecules.

Telomerase is expressed in more than 90 percent of human cancers, and may be an important factor in the ability of cancer cells to divide continuously. Since most normal cells do not have this ability, telomerase is an attractive target for drugs designed to attack tumors specifically. There is also interest in telomerase and aging. When cultured human cells are transformed with a telomerase gene that is expressed at high levels, their telomeres do not shorten. Instead of living 20 to 30 cell generations and then dying, the cells become immortal. It remains to be seen how this finding relates to the aging of a whole organism.

13.3 recap

Meselson and Stahl showed that DNA replication is semiconservative: each parent DNA strand serves as a template for a new strand. A complex of proteins, most notably DNA polymerase, is involved in replication. New DNA is polymerized in one direction only, and since the two strands are antiparallel, one strand is made continuously and the other is synthesized in short Okazaki fragments that are eventually joined.

learning outcomes

You should be able to:

- Explain why the Meselson–Stahl experiment provided evidence in support of only one model of DNA replication.
 - Identify the function of each component needed for DNA replication.
 - Explain the roles of DNA helicases and single-stranded binding proteins.
 - Explain the need for telomerases as a consequence of the semiconservative replication of DNA.
-

1. How did the Meselson–Stahl experiment differentiate between the three models for DNA replication?
2. Name five proteins needed for DNA replication. What are their roles?
3. Why are there special sequences at the ends of chromosomes, and how are they replicated?
4. The drug dideoxycytidine, used to treat certain viral infections, is a nucleotide made with 2',3'-dideoxyribose. This sugar lacks —OH groups at both the 2' and the 3' positions. Explain why this drug stops the growth of a DNA chain when added to DNA.

The complex process of DNA replication is amazingly accurate, but it is not perfect. What happens when things go wrong?

13.4 Errors in DNA Can Be Repaired

DNA must be accurately replicated and maintained. This is essential for the proper functioning of every cell, whether a prokaryote or a cell in a complex, multicellular organism. Yet the replication of DNA is not perfectly accurate, and DNA is subject to change by chemicals and other environmental agents. In the face of these threats, how has life gone on for so long?

focus your learning

Errors in DNA can occur during replication and as the result of chemical changes in bases.

Repair mechanisms preserve DNA

DNA polymerases make mistakes in assembling polynucleotide strands—typically about 1 wrong base is inserted per 100,000 replicated. While this may seem insignificant considering that a human cell has around 3 billion base pairs, the mistakes add up: if polymerase mistakes were not repaired, there would be about 60,000 incorrect bases in new strands every time a human cell divided. It gets worse: errors in base pairs can arise spontaneously as well. Because the bases themselves are chemically instable, outside agents like radiation can damage them, causing ***mutations** that prevent them from pairing properly.

Fortunately, our cells correct DNA replication errors and repair damaged nucleotides. Cells have at least three DNA repair mechanisms at their disposal:

- A **proofreading** mechanism corrects errors in replication as DNA polymerase makes them.
- A **mismatch repair** mechanism scans DNA immediately after it has been replicated and corrects any base-pairing mismatches.
- An **excision repair** mechanism removes abnormal bases that have formed because of chemical damage and replaces them with functional bases.

proofreading During DNA replication, a mechanism that excises a base that is incorrectly inserted according to the template (e.g., an A opposite a template G) and inserts the correct base (e.g., C opposite template G).

mismatch repair A mechanism that scans DNA after it has been replicated and corrects any base-pairing mismatches.

excision repair DNA repair mechanism that removes damaged DNA and replaces it with the appropriate nucleotide.

Most DNA polymerases perform a proofreading function each time they introduce a new nucleotide into a growing DNA strand (**Figure 13.18A**). When a DNA polymerase recognizes a mispairing of bases, it removes the improperly introduced nucleotide and tries again. (Other proteins in the replication complex also play roles in proofreading.) The error rate for this process is only about 1 in 10,000 repaired base pairs, and it lowers the overall error rate for replication to about one error in every 10^{10} bases replicated.

After the DNA has been replicated, a second set of proteins surveys the newly replicated

molecule and looks for mismatched base pairs that were missed in proofreading ([Figure 13.18B](#)). For example, this mismatch repair mechanism might detect an A-C base pair instead of an A-T pair. The repair system recognizes which of the two bases in the A-C pair is the wrong one and makes the repair. If the correct pair should be A-T, the repair system replaces C with T, restoring an A-T pair. Alternatively, if it recognizes that the correct pair should be C-G, it replaces A with G. When mismatch repair fails, DNA sequences are altered. One form of colon cancer arises in part from a failure of mismatch repair.

DNA molecules can also be damaged during the life of a cell (e.g., when it is in G1). High-energy radiation, chemicals from the environment, and spontaneous chemical changes can damage DNA. For example, when adjacent thymines on the same DNA strand absorb ultraviolet light (at about 260 nm), they form a covalent bond between the bases, making a thymine dimer. These dimers interfere with base pairing during replication, leading to random bases being inserted. This is the primary cause of skin cancer in humans. Excision repair mechanisms deal with these kinds of damage ([Figure 13.18C](#)).

13.4 recap

DNA replication is not perfect. In addition, DNA may be altered or damaged by environmental factors. Repair mechanisms detect and repair mismatched or damaged DNA.

learning outcomes

- Predict the consequences of DNA errors if not corrected.
1. From what you know about the role of DNA in the cell, what would be the genetic consequences of an unrepaired DNA change in S phase before meiosis?
 2. One form of colon cancer is caused by a mutation in a gene encoding a protein involved in mismatch repair. What would be the consequences of such a mutation in cancer formation? Recall cell cycle control genes involved in cancer formation (see [Figure 11.24](#)).

Understanding how DNA is replicated and repaired has allowed scientists to develop techniques for studying genes. We'll look at just one of those techniques next.

***connect the concepts** The molecularbiology of DNA mutations is discussed in [Key Concept 15.1](#) and the genetic consequences of mutations in [Key Concept 12.2](#).

13.5 The Polymerase Chain Reaction Amplifies DNA

The principles underlying DNA replication in cells have been used to develop an important laboratory technique that has been vital in analyzing genes and genomes. This technique allows researchers to make multiple copies of short DNA sequences.

focus your learning

The polymerase chain reaction was developed for the purpose of rapidly making multiple copies of segments of DNA.

 **Activity 13.2 Polymerase Chain Reaction Simulation** www.Life11e.com/ac13.2

The polymerase chain reaction can make multiple copies of a DNA sequence

In order to study DNA and perform genetic manipulations in the lab, it is often necessary to make multiple copies of a DNA sequence. DNA amplification is needed because the amount of DNA isolated from a biological sample is often too small to work with. The [polymerase chain reaction \(PCR\)](#) technique essentially automates this replication process by copying a short region of DNA many times in a test tube. The PCR reaction mixture contains:

polymerase chain reaction (PCR) An enzymatic technique for the rapid production of millions of copies of a particular stretch of DNA where only a small amount of the parent molecule is available.

A sample of double-stranded DNA from a biological sample, to act as the template

Two short, artificially synthesized primers that are complementary to the ends of the sequence to be amplified

The four dNTPs (dATP, dTTP, dCTP, and dGTP)

A DNA polymerase that can tolerate high temperatures without becoming degraded

Salts and a buffer to maintain a near-neutral pH

PCR amplification is a cyclic process in which a sequence of steps is repeated over and over ([Figure 13.19](#)):

Figure 13.19 The Polymerase Chain Reaction The steps in this cyclic process are repeated many times to produce multiple identical copies of a DNA fragment. This makes enough DNA for chemical analysis and genetic manipulations.

Q: How do PCR primers relate to DNA replication primers?

- The first step involves heating the reaction mixture to near boiling point, to separate (denature) the two strands of the DNA template.
- The reaction is then cooled to allow the primers to bind (or anneal) to the template strands.
- Next, the reaction is warmed to an optimum temperature for the DNA polymerase to catalyze the production of the complementary new strands.

A single cycle takes a few minutes to produce two copies of the target DNA sequence, leaving the new DNA in the double-stranded state. Repeating the cycle many times leads to an exponential increase in the number of copies of the DNA sequence.

The PCR technique requires that the base sequences at the 3' end of each strand of the target DNA sequence be known, so that complementary primers, usually 15 to 30 bases long, can be made in the laboratory. Because of the uniqueness of DNA sequences, a pair of primers this length will usually bind to only a single region of DNA in an organism's genome. This specificity, despite the incredible diversity of DNA sequences, is a key to the power of PCR.

One initial problem with PCR was its temperature requirements. To denature DNA, it must be heated to more than 90°C—a temperature that destroys most DNA polymerases. When the PCR technique was first being developed, new enzyme had to be added after denaturation in each cycle, which made the technique impractical for widespread use. This problem was solved by nature: in the hot springs at Yellowstone National Park, as well as in other high-temperature locations, there lives a bacterium called, appropriately, *Thermus aquaticus* ("hot water"). The means by which this organism survives temperatures of up to 95°C was investigated by Thomas Brock and his colleagues at the University of Wisconsin, Madison. They discovered that *T. aquaticus* has metabolic machinery that is heat-resistant, including a DNA polymerase that does not denature at these high temperatures.

Scientists pondering the problem of copying DNA by PCR read Brock's basic research articles and got a clever idea: why not use *T. aquaticus* DNA polymerase in the PCR technique? It could withstand the 90°C denaturation temperature and would not have to be added during each cycle. The idea worked, and it earned biochemist Kary Mullis a Nobel prize. PCR has had an enormous impact on genetic research. Some of its most striking applications will be described in

[Chapters 15–18](#). These applications range from amplifying DNA in order to identify an individual person or organism, to detection of diseases.

13.5 recap

Knowledge of the mechanisms of DNA replication led to the development of a technique for making multiple copies of DNA sequences.

learning outcomes

You should be able to:

- Explain the purpose for each step in the PCR process.
- Explain why PCR is useful in different research scenarios.

1. What is the role of primers in PCR?
2. One way to quickly identify an organism in the field is to use PCR: If there is amplification of a particular sequence, then the organism is identified. What is the basis for this test?

investigatinglife

What do we need to know about DNA replication to describe the mechanism of a drug that blocks it?

Recall that the opening story to this chapter described the discovery that platinum electrodes inhibit cell division, which lead researchers to wonder if they could invent a drug containing platinum that might inhibit the uncontrolled growth of cancer cells. The drug that Dr. Barnett Rosenberg developed, cisplatin, was remarkably efficient at halting certain kinds of tumor growth. Understanding how cisplatin works came with an understanding of the chemistry of DNA and the mechanism by which it replicates.

Investigating Life: The Meselson–Stahl Experiments discusses the experiments which revealed that DNA replicates semiconservatively—that separated strands of DNA serve as templates for new strands. We mentioned also the finding that semiconservative replication does not occur in the presence of cisplatin, suggesting that cisplatin interferes with strand separation, which is a prerequisite for replication. How does this come about, and what does it have to do with platinum?

Cisplatin contains a platinum atom bonded to two amino groups and two chlorine atoms ([Figure 13.20A](#)). In Rosenberg's experiments, this compound was formed when the platinum electrode reacted with salts in the surrounding solution. The bonds between the platinum atom and the chlorine atoms are weak, and the latter can be displaced by electron-rich substances (you may know from chemistry that these are called nucleophiles). In DNA, one of the nitrogen atoms of guanine ([Figure 13.20B](#)) displaces one of the chlorines, forming a strong covalent bond. If there is a nearby guanine on the opposite DNA strand, the other chlorine of the cisplatin molecule can be displaced as well, so that the cisplatin is effectively bonded to both of the DNA strands. In short, the DNA strands become cross-linked and cannot separate as needed for DNA replication ([Figure 13.20C](#)). Without replication, the cell cannot divide, and it undergoes apoptosis. The type of DNA lesion caused by cisplatin cannot be repaired by any of the cell's usual DNA repair mechanisms.

(A) Cisplatin

(B) Guanine

(C) Cross-linking of the DNA strands by cisplatin

Figure 13.20 Cisplatin: A Small but Lethal Molecule

Future directions

Eukaryotic chromosomes have long strands of DNA, each with up to tens of millions of base pairs. During S phase of the cell cycle, each chromosome must be replicated only once and completely. Since replication is bidirectional from an origin, and since S phase typically is not long enough to replicate an entire chromosome, there must be many starting points for replication. Understanding how this happens is a major challenge for biologists. A recent discovery may give a clue as to how a DNA replication complex arrives at each replication origin. While most RNA molecules transcribed from DNA leave their site of synthesis, some do not. These short RNAs, complementary to their DNA template, turn back instead and bind to the DNA by base pairing. Indeed, this rapid binding displaces the non-template strand of DNA, so it forms a loop. At these spots on the long chromosome, there are loops with a region of DNA that is unpaired with its complementary strand, because that strand at that location is bound up with RNA emerging evidence suggests that the "R-loops," with their exposed DNA bases, act to recognize binding of the proteins of the DNA replication complex.

▶ 13.1 Experiments Revealed the Function of DNA as Genetic Material

- Griffith's experiments in the 1920s demonstrated that some substance in cells can cause heritable changes in other cells. [Review Figure 13.1](#)
- The location and quantity of DNA in the cell suggested that DNA might be the genetic material. Avery and his colleagues isolated the transforming principle from bacteria and identified it as DNA. [Review Figure 13.2](#)
- The Hershey–Chase experiments established conclusively that DNA (and not protein) is the genetic material, by tracing the DNA of radioactively labeled viruses, which were used to infect bacterial cells. [Review Figure 13.4](#), [Animation 13.1](#)
- Genetic transformation of eukaryotic cells is often called transfection. Transformation and transfection can be studied with the aid of a [genetic marker](#) gene that confers a known and observable phenotype.

genetic marker (1) In gene cloning, a gene of identifiable phenotype that indicates the presence of another gene, DNA segment, or chromosome fragment. (2) In general, a DNA sequence such as a single nucleotide polymorphism whose presence is correlated with the presence of other linked genes on that chromosome.

▶ 13.2 DNA Has a Structure That Suits Its Function

- Chargaff's rule states that the amount of [adenine](#) in DNA is equal to the amount of [thymine](#), and that the amount of [guanine](#) is equal to the amount of [cytosine](#); thus the total abundance of purines (A + G) equals the total abundance of pyrimidines (T + C).

adenine (A) (a' den een) A nitrogen-containing base found in nucleic acids, ATP, NAD, and other compounds.

thymine (T) Nitrogen-containing base found in DNA.

guanine (G) (gwan' een) A nitrogen-containing base found in DNA, RNA, and GTP.

cytosine (C) (site' oh seen) A nitrogen-containing base found in DNA and RNA.

- X-ray diffraction showed that the DNA molecule is a double helix. Watson and Crick proposed that the two strands in DNA are **anti-parallel**. [Review Figure 13.6](#)
- [Complementary base pairing](#) between A and T and between G and C accounts for Chargaff's rule. The bases are held together by hydrogen bonding.

complementary base pairing The AT (or AU), TA (or UA), CG, and GC pairing of bases in double-stranded DNA, in transcription, and between tRNA and mRNA.

- Reactive groups are exposed in the paired bases, allowing for recognition by other molecules such as proteins. [Review Figure 13.7](#)

▶ 13.3 DNA Is Replicated Semiconservatively

See [Animation 13.2](#)

- Meselson and Stahl showed that DNA undergoes [semiconservative replication](#). Each parent strand acts as a [template](#) for the synthesis of a new strand; thus the two replicated DNA molecules each contain one parent strand and one newly synthesized strand. **Review Investigating Life: The Meselson–Stahl Experiment**, [Animation 13.3](#)

semiconservative replication The way in which DNA is synthesized. Each of the two partner strands in a double helix acts as a template for a new partner strand. Hence, after replication, each double helix consists of one old and one new strand.

template A molecule or surface on which another molecule is synthesized in complementary fashion, as in the replication of DNA.

- In DNA replication, the enzyme [DNA polymerase](#) catalyzes the addition of nucleotides to the 3' end of each strand. Which nucleotides are added is determined by complementary base pairing with the template strand. **Review Figure 13.9**

DNA polymerase Any of a group of enzymes that catalyze the formation of DNA strands from a DNA template.

- The pre-replication complex is a huge protein complex that attaches to the chromosome at the [origin of replication \(ori\)](#).

origin of replication (ori) DNA sequence at which helicase unwinds the DNA double helix and DNA polymerase binds to initiate DNA replication.

- Replication proceeds from the origin of replication on both strands in the 5'-to-3' direction, forming a [replication fork](#). **Review Figure 13.10**

replication fork A point at which a DNA molecule is replicating. The fork forms by the unwinding of the parent molecule.

- [Primase](#) catalyzes the synthesis of a short RNA [primer](#) to which nucleotides are added by DNA polymerase. **Review Figure 13.11**

primase (prigh' maze) An enzyme that catalyzes the synthesis of a primer for DNA replication.

primer Strand of nucleic acid, usually RNA, that is the necessary starting material for the synthesis of a new DNA strand, which is synthesized from the 3' end of the primer.

- Many proteins assist in DNA replication. [DNA helicase](#) separates the strands, and [single-strand binding proteins](#) keep the strands from reassociating. **Review Figure 13.13, Activity 13.1**

DNA helicase An enzyme that unwinds the double helix.

single-strand binding protein In DNA replication, a protein that binds to single strands of DNA

after they have been separated from each other, keeping the two strands separate for replication.

- The **leading strand** is synthesized continuously and the **lagging strand** in pieces called **Okazaki fragments**. The fragments are joined together by **DNA ligase**. **Review Focus: Key Figure 13.13, Figure 13.14, Animation 13.4**

leading strand In DNA replication, the daughter strand that is synthesized continuously. (Contrast with lagging strand.)

lagging strand In DNA replication, the daughter strand that is synthesized in discontinuous stretches. (See Okazaki fragments. Contrast with leading strand.)

Okazaki fragments Newly formed DNA making up the lagging strand in DNA replication. DNA ligase links Okazaki fragments together to give a continuous strand.

DNA ligase Enzyme that unites broken DNA strands during replication and recombination.

- The speed with which DNA polymerization proceeds is attributed to the **processive** nature of DNA polymerases, which can catalyze many polymerizations at a time. A **sliding DNA clamp** helps ensure the stability of this process. **Review Figure 13.16**

processive Pertaining to an enzyme that catalyzes many reactions each time it binds to a substrate, as DNA polymerase does during DNA replication.

sliding DNA clamp Protein complex that keeps DNA polymerase bound to DNA during replication.

- At the ends of eukaryotic chromosomes are regions of repetitive DNA sequence called **telomeres**. Unless the enzyme **telomerase** is present, a short segment at the end of each telomere is lost each time the DNA is replicated. After multiple cell cycles, the telomeres shorten enough to cause chromosome instability and cell death. **Review Figure 13.17**

telomeres (tee' lo merz) [Gk. *telos*: end + *meros*: units, segments] Repeated DNA sequences at the ends of eukaryotic chromosomes.

telomerase An enzyme that catalyzes the addition of telomeric sequences lost from chromosomes during DNA replication.

▶ 13.4 Errors in DNA Can Be Repaired

- DNA polymerases make about one error in 100,000 bases replicated. DNA is also subject to natural alterations and chemical damage. DNA can be repaired by at least three different mechanisms: **proofreading**, **mismatch repair**, and **excision repair**. **Review Figure 13.18**

proofreading During DNA replication, a mechanism that excises a base that is incorrectly inserted according to the template (e.g., an A opposite a template G) and inserts the correct base (e.g., C opposite template G).

excision repair DNA repair mechanism that removes damaged DNA and replaces it with the appropriate nucleotide.

▶ 13.5 The Polymerase Chain Reaction Amplifies DNA

- The [polymerase chain reaction](#) technique uses DNA polymerase to make multiple copies of DNA in the laboratory. **Review** [Figure 13.19](#), [Activity 13.2](#)

polymerase chain reaction (PCR) An enzymatic technique for the rapid production of millions of copies of a particular stretch of DNA where only a small amount of the parent molecule is available.

► Apply What You've Learned

Review

3.3 DNA replication proceeds bidirectionally from an origin of replication (*ori*); *E. coli* has a single *ori*, and eukaryotic chromosomes have multiple ones.

Original Paper:Original Paper: Huberman, J. A. and Riggs A. D. 1968. On the mechanism of DNA replication in mammalian chromosomes. *Journal of Molecular Biology* 32: 327–341.

Biologists use a variety of methods to develop hypotheses about living systems. A mathematical approach, for example, can help you learn about DNA replication in human cells.

DNA replication is not an ongoing process in cells but is restricted to the S phase of the cell cycle. Typically, in dividing mammalian cells, S phase is 8 hours long. The rate at which DNA polymerase links nucleotides to form a new strand of DNA is about 50 base pairs per second. The shortest chromosomal DNA in a human cell contains approximately 50×10^6 base pairs; the longest chromosome contains approximately 250×10^6 base pairs.

Questions

1. Using the information above, calculate how long will it take a single DNA polymerase to replicate the entire DNA molecule in the shortest chromosome if it starts at one end of the DNA molecule and proceeds uninterrupted to the other end. Compare this to the 8 hours that the cell has to complete its DNA replication. Do the results suggest that DNA replication involves just one starting point, or do they point to an alternate hypothesis?

Now consider the results from an investigation. As you know, thymine is one of the four bases in DNA. In the lab, scientists can replace the normal isotope of hydrogen (^1H) with the radioactive isotope (^3H) in thymidine, the nucleotide containing the base thymine. If dividing cells in S phase are given all four nucleotides, but with ^3H -thymidine for a short time (called a “pulse”), the newly synthesized DNA strand will be radioactive. The radioactive strand can be viewed under the microscope by a special process if the DNA is spread out on a microscope slide.

2. The diagram below shows radioactivity for a small segment of a single DNA strand extracted from human S phase cells after a pulse with ^3H -thymidine during the last 4 hours of S phase.

What can you conclude about the number of starting points on a single DNA molecule? Is this consistent with your results in question 1?

In a second experiment, the cells were given a pulse with ^3H -thymidine just after they began S phase. After several hours the cells were given non-radioactive ^1H -thymidine (a “chase” to follow the “pulse”), so DNA made from that point on was not labeled. After some time, the DNA was extracted and the same chromosome was examined. The diagram below shows the results of this experiment on the same small segment of a single DNA strand as above.

3. Was DNA replication unidirectional or bidirectional from its starting point? Explain your answer.
4. Draw the double-stranded DNA that would result from the second experiment, showing where labeled and unlabeled nucleotides would be found.

Employing the Genetic Code to Combat Superbugs

Staphylococcus aureus is among billions of bacteria that inhabit the human skin and nose, mostly with no ill effect. But sometimes, especially when the immune system has been weakened by age or disease, *S. aureus* can cause major skin infections and may enter the body through the nose or a wound site, causing serious and sometimes fatal infections of organs such as the heart and lungs.

Until recently, most *S. aureus* infections were successfully treated with penicillin and related drugs, including methicillin. These antibiotics bind and inactivate several related enzymes involved in the assembly of bacterial cell walls. New bacterial cells produced by cell division of antibiotic-treated bacteria do not survive.

Unfortunately, some *S. aureus* strains have acquired mutant versions of a penicillin-binding protein that are resistant to antibiotics—the mutant enzyme can catalyze the assembly of cell walls even in the presence of antibiotics. The mutant *mecA* gene that encodes this mutant protein can be passed from one bacterium to another by bacterial conjugation (see [Key Concept 12.6](#)).

What makes the mutant version of *mecA* different, and how does this difference lead to antibiotic resistance? Compared to the wild-type allele, the mutant *mecA* gene has a small change in its nucleotide sequence. This results in changes in the amino acid sequence of the expressed protein. This alteration in the protein's secondary structure affects its tertiary structure: the protein folds into a shape that doesn't bind the antibiotics.

The fundamental lesson conveyed by this example is that *a gene is expressed as a protein*, and more specifically, that *the sequence of nucleotides in DNA is expressed as a sequence of amino acids in a protein*. Understanding how the nucleotide sequence of a gene produces a specific protein came with the discovery of the genetic code, a landmark in biological research.

Mutant bacterial strains that are stubbornly resistant to antibiotics are known as “superbugs.” One greatly feared superbug is methicillin-resistant *S. aureus*, or MRSA. About 1 person in 50 carries MRSA, so it represents a real threat to public health. MRSA incidence is declining, thanks to careful monitoring and treatment in hospitals and nursing homes, where people are especially vulnerable. The infection is treated with a new class of antibiotics that target bacterial protein synthesis.

QA How does knowledge of the genetic code help us understand the actions of some antibiotics?

14.1 Genes Code for Proteins

In [Chapter 4](#) we introduced DNA and its role in gene expression. Then in [Chapter 13](#) we presented evidence that DNA is the carrier of genetic information and described how DNA is replicated prior to cell division. Here we will focus on the evidence that proteins are the major products of gene expression, and we will describe how a gene is expressed as protein.

focus your learning

Experimental evidence supports the claim that each gene encodes one protein.

Scientists had a molecular understanding of phenotypes before it was known that DNA was the genetic material; they had studied the chemical differences between individuals carrying wild-type and mutant alleles in organisms as diverse as humans and bread molds and knew that the major phenotypic differences resulted from differences in specific proteins. But just *how* different proteins arise in different individuals was not understood.

Observations in humans led to the proposal that genes determine enzymes

The identification of a gene product as a protein began with a mutation. In the early twentieth century, English physician Archibald Garrod saw several children with a rare disease. One symptom of the disease was that the urine turned dark brown when exposed to air, which was especially noticeable on the infants' diapers. The disease was given the descriptive name alkaptonuria ("black urine").

Garrod noticed that the disease was most common in children whose parents were first cousins. Mendelian genetics had just been "rediscovered," and Garrod realized that because first cousins share on average 1/8 of their alleles, the children of first cousins might inherit a rare mutant allele from both parents. He proposed that alkaptonuria was a recessive phenotype caused by a mutant allele that causes the disease phenotype.

Garrod took the analysis further by identifying the biochemical abnormality in the affected children. He isolated from them an unusual substance, homogentisic acid, which accumulated in blood, joints (where it crystallized and caused severe pain), and urine (where it turned black). The chemical structure of homogentisic acid is similar to that of the amino acid tyrosine:

Homogentisic acid

The function of enzymes as biological catalysts had just been discovered. Garrod proposed that homogentisic acid was a breakdown product of tyrosine. He suggested that while homogentisic acid ordinarily would be converted to a harmless product, it was not being converted in children with alkaptonuria. Garrod further hypothesized that the enzyme required for the breakdown of homogentisic acid was not being produced in these children. He suggested that a normal human allele (for the wild-type phenotype) was required for the synthesis of an enzyme that catalyzed this conversion:

If the allele were mutated, the enzyme would be inactive and homogentisic acid would accumulate instead:

Garrod concluded that there must be *one gene to one enzyme* and coined the term “inborn error of metabolism” to describe this genetically determined biochemical disease. But his hypothesis was not confirmed until the actual enzyme and the specific gene mutation involved were identified. The enzyme, homogentisic acid oxidase, was identified as active in healthy people and inactive in alkaptonuria patients in 1958, and the specific DNA mutation was described in 1996.

To relate genes and enzymes more generally, biologists turned to simpler organisms that could be manipulated in the laboratory.

Experiments on bread mold established that genes determine enzymes

As they work to explain the principles that govern life, biologists often turn to organisms that are easy to manipulate experimentally. Such [model organisms](#) have certain characteristics that make them attractive experimental subjects. For example, model organisms:

model organisms Also known as **model systems**, these include the small group of species that are the subject of extensive research. They are organisms that adapt well to laboratory situations and findings from experiments on them can apply across a broad range of species. Classic examples include white mice and the fruit fly *Drosophila*.

are easy to grow in the laboratory or greenhouse.

have short generation times.

are easy to manipulate genetically, by crossing or by other methods.

often produce large numbers of progeny.

Biologists have used model organisms to develop principles of genetics that can then be applied more generally to other organisms. You have seen some of these organisms in previous chapters:

Pea plants (*Pisum sativum*) were used by Mendel in his genetics experiments.

Fruit flies (*Drosophila*) were used by Morgan in his genetics experiments.

Escherichia coli was used by Meselson and Stahl to study DNA replication.

To this list we now add the bread mold *Neurospora*, an ascomycete fungus (see [Chapter 30](#)). This mold is haploid for most of its life cycle, so there are no dominant or recessive alleles: all alleles are expressed phenotypically and not masked by a heterozygous condition. *Neurospora* is easy to grow in the laboratory. Biologists at Stanford University led by George Beadle and Edward Tatum undertook studies to biochemically define the phenotypes in *Neurospora*.

Like Garrod, Beadle and Tatum hypothesized that the expression of a specific gene results in the activity of a specific enzyme. They set out to test this hypothesis directly. They grew *Neurospora* on a nutritional medium containing sucrose, minerals, and biotin, which is the only vitamin that wild-type *Neurospora* cannot synthesize itself. Using this minimal medium, the enzymes of wild-type *Neurospora* could catalyze all the metabolic reactions needed for growth.

The scientists then treated the wild-type *Neurospora* with X rays, which function as a mutagen. A [mutagen](#) is something that damages DNA, causing [mutations](#): heritable alterations in the DNA sequence. After the X-ray treatment, some *Neurospora* strains could no longer grow on the minimal medium. These mutant strains grew only if they were supplied with specific additional nutrients, such as particular vitamins. Beadle and Tatum hypothesized that these genetic strains had mutations in the genes that code for production of enzymes needed to synthesize the additional nutrients. For each mutant strain, the scientists were able to find a single compound that, when added to the minimal medium, supported the growth of that strain. These results suggested that mutations have simple effects, and that each mutation causes a defect in only one enzyme in a metabolic pathway. These conclusions confirmed Garrod's **one-gene, one-enzyme hypothesis**.

mutagen (mute' ah jen) [L. *mutare*: change + Gk. *genesis*: source] Any agent (e.g., a chemical, radiation) that increases the mutation rate.

mutation A change in the genetic material not caused by recombination.

Mutations provide a powerful way to determine cause and effect in biology. Nowhere has this been more evident than in the elucidation of biochemical pathways. Such pathways consist of sequential events (chemical reactions) in which each event is dependent on the occurrence of the preceding event. The general reasoning is as follows:

Observation. A particular gene (a) is present and a particular reaction catalyzed by a particular enzyme (A) occurs; the two are correlated.

Hypothesis. Gene a determines the synthesis of enzyme A.

Test of hypothesis. Mutate gene a. Prediction: no functional enzyme is made, and the reaction does not occur.

Two colleagues of Beadle and Tatum, Adrian Srb and Norman Horowitz, used this experimental approach to isolate *Neurospora* mutants that could not survive without the amino acid arginine in their growth medium. By adding particular compounds to the medium, Srb and Horowitz were able to identify a series of steps in the biochemical pathway leading to the synthesis of arginine ([Figure 14.1](#)).

Figure 14.1A One Gene, One Enzyme

Original Paper: Srb, A. M. and N. H. Horowitz. 1944. The ornithine cycle in *Neospora* and its genetic control. *Journal of Biological Chemistry* 154: 129–139.

Srb and Horowitz developed several mutant strains of *Neurospora* that could not make arginine (arg). Several molecules including ornithine and citrulline are needed for arginine synthesis. By systematically adding each of these molecules to the growth media for the mutant strains, the researchers deduced that each mutant strain was deficient in one enzyme along a biochemical pathway.

HYPOTHESIS ▶ Each gene determines an enzyme in a biochemical pathway.

METHOD Place spores (single cells that divide to produce mold colonies) of each arg mutant strain on a minimal nutritional medium with and without supplements.

RESULTS

INTERPRETATION

If an organism cannot convert one particular compound to another, it presumably lacks an enzyme required for conversion, and the mutation is in the gene that codes for that enzyme.

CONCLUSION ▶ Each gene specifies a particular enzyme.

Figure 14.1B **work with the data** follows on next page.

work with the data

Figure 14.1B One Gene, One Enzyme

Original Paper: Srb, A. M. and N. H. Horowitz. 1944.

Neurospora (left) is haploid for most of its life cycle, except for the formation of a diploid cell when it undergoes mating; the cell then undergoes meiosis to form haploid spores. Beadle and Tatum used X rays to cause mutations in *Neurospora*. They isolated mutant strains that were unable to grow on minimal medium but were able to grow if

the medium was supplemented with particular compounds. Their colleagues Adrian Srb and Norman Horowitz analyzed 15 mutant strains (the *arg* mutants) that could not synthesize arginine but could grow on medium supplemented with arginine. The scientists tested various compounds and found two, ornithine and citrulline, that could be used instead of arginine to support the growth of some of the mutant strains (as seen Figure 14.1A). The results for three of the strains are shown in the first three rows of the table, with growth expressed as dry weight of fungal material after growth for 5 days.

Strain	No addition	Ornithine added	Citrulline added	Arginine added
34105	1.1	25.5	30.0	33.2
33442	2.3	2.5	42.7	43.8
36703	0.0	0.0	0.0	20.4
Double mutant	0.0	0.0	0.0	22.0

QUESTIONS

1. Based on the biochemical pathway for arginine synthesis shown in the experiment (Figure 14.1A), which gene (a, b, or c) encoding proteins (A, B, or C) was mutated in each strain?
2. Why was there some growth in strains 34105 and 33442 even when there were no additions to the growth medium?
3. Nineteen other amino acids were tested as substitutes for arginine in the three strains. In all cases, there was no growth. Explain these results.
4. Sexual reproduction in *Neurospora* was used to create double mutants, which carried the mutations from both parental strains. A double mutant derived from strains 33442 and 36703 had the growth characteristics shown in the last row of the table. Explain these data in terms of the genes, mutations, and biochemical pathway.

A similar **work with the data** exercise may be assigned in **LaunchPad**.

One gene determines one polypeptide

The one-gene, one-enzyme relationship has undergone several modifications in light of our current knowledge of molecular biology. Many proteins, including many enzymes, are composed of more than one ***polypeptide chain**, or subunit. So it is more correct to speak of a **one-gene, one-polypeptide relationship**.

So far we have seen that in terms of protein synthesis, the *function of a gene is to prescribe the production of a single, specific polypeptide*. But not all genes code for polypeptides. As we will see below and in [Chapter 16](#), many DNA sequences are transcribed to RNA molecules that are not translated into polypeptides, but instead have other functions.

14.1 recap

Studies of mutations in humans and bread molds led to our understanding of the one-gene, one-polypeptide relationship. In most cases, the function of a gene is to code for a specific polypeptide.

learning outcomes

You should be able to:

- Justify the selection of various model organisms used for genetic studies.
 - Explain how experimental design has played an important role in enabling researchers to elucidate information about metabolic pathways.
 - Analyze data to link genes to their products.
1. What is a model organism, and why is *Neurospora* a good model for studying biochemical genetics?
 2. How were the experiments on mutant strains of *Neurospora* set up to determine the order of steps in a biochemical pathway?
 3. Beadle and Tatum's experiments showed that a biochemical pathway could be deduced

from mutant strains. In bacteria, the biosynthesis of the amino acid tryptophan (T) from the precursor chorismate (C) involves four intermediate chemical compounds, which we will call D, E, F, and G. Here are the phenotypes of various mutant strains. Each strain has a mutation in a gene for a different enzyme; + means growth with the indicated compound added to the medium, and 0 means no growth. Based on these data, order the compounds (C, D, E, F, G, and T) and enzymes (1, 2, 3, 4, and 5) in a biochemical pathway.

Mutant strain	Addition to medium					
	C	D	E	F	G	T
1	0	0	0	0	+	+
2	0	+	+	0	+	+
3	0	+	0	0	+	+
4	0	+	+	+	+	+
5	0	0	0	0	0	+

Now that you have seen the evidence for the one-gene, one-polypeptide relationship, how does it work? That is, how is the information encoded in DNA used to produce a particular polypeptide?

***connect the concepts** Hemoglobin, illustrated in [Figure 3.11](#) is an example of a protein composed of more than one polypeptide chain. Hemoglobin has four polypeptides—two α and two β subunits, and each subunit is encoded by a separate gene.

14.2 Information Flows from Genes to Proteins

As we discussed in [Chapter 13](#) and [Key Concept 14.1](#), DNA is the hereditary material and codes for proteins and RNAs. In the remainder of this chapter we will focus on the processes that occur when a protein-coding gene is expressed. We briefly outlined gene expression in [Key Concept 4.1](#). To review, this process occurs in two major steps:

- During [transcription](#), the information in a DNA sequence (a gene) is copied into a complementary RNA sequence.
- During [translation](#), this RNA sequence is used to create the amino acid sequence of a polypeptide.

transcription The synthesis of RNA using one strand of DNA as a template.

translation The synthesis of a protein (polypeptide). Takes place on ribosomes, using the information encoded in messenger RNA.

Francis Crick and James Watson, who deciphered the structure of DNA, first proposed this model for gene expression. They took the concept further by suggesting that gene expression can go in only one direction: DNA can be used to create a protein, but a protein can never be used to create DNA. At the time, Crick called this “the [central dogma](#) of molecular biology.”

central dogma The premise that information flows from DNA to RNA to polypeptide (protein).

focus your learning

Gene expression involves the processes of transcription and translation.

Some virus genomes are composed of single-strand RNA, which is used to direct DNA synthesis by reverse transcription when the virus infects a host cell.

Three types of RNA have roles in the information flow from DNA to protein

There are numerous types of RNA. Three of them have vital roles in gene expression.

MESSENGER RNA AND TRANSCRIPTION

When a protein-coding gene is expressed, one of the two DNA strands in the gene is transcribed to produce a complementary RNA strand, which is then processed to produce [messenger RNA \(mRNA\)](#). In eukaryotic cells, the mRNA travels from the nucleus to the cytoplasm, where it is translated into a polypeptide (**Focus: Key Figure 14.2**). The nucleotide sequence of the mRNA determines the ordered sequence of amino acids in the polypeptide chain, which is built by a ribosome.

messenger RNA (mRNA) Transcript of a region of one of the strands of DNA; carries information (as a sequence of codons) for the synthesis of one or more proteins.

focus: key figure

Figure 14.2 From Gene to Protein This diagram summarizes the processes of gene expression in eukaryotes. Note that the nucleus is typically about 1/10 the size shown here.

Q: In general, how would this diagram be different for a prokaryotic cell?

RIBOSOMAL RNA AND TRANSLATION

The **ribosome** is essentially a protein synthesis factory composed of multiple proteins and several **ribosomal RNAs (rRNAs)**. One of the rRNAs catalyzes peptide bond formation between amino acids, to form a polypeptide.

ribosome A small particle in the cell that is the site of protein synthesis.

ribosomal RNA (rRNA) Several species of RNA that are incorporated into the ribosome. Involved in peptide bond formation.

TRANSFER RNA MEDIATES BETWEEN mRNA AND PROTEIN

Another type of RNA called **transfer RNA (tRNA)** can both bind a specific amino acid and recognize specific sequences of nucleotides in mRNA. It is the tRNA that recognizes which amino acid should be added next to a growing polypeptide chain.

transfer RNA (tRNA) A family of folded RNA molecules. Each tRNA carries a specific amino acid and anticodon that will pair with the complementary codon in mRNA during translation.

Media Clip 14.1 Protein Synthesis: An Epic on a Cellular Level

www.Life11e.com/mc14.1

In some cases, RNA determines the sequence of DNA

While we have said that DNA is the genetic material, some viruses present exceptions to the general process of gene expression outlined above. As we saw in [Key Concept 13.1](#), a virus is a non-cellular infectious particle that reproduces inside cells. Many viruses, such as the ones that cause influenza and polio, have RNA rather than DNA as their genetic material. That is, the nucleotide sequence of viral RNA acts as an information carrier and can be expressed as a protein. Because RNA is usually single-stranded, the question arises: how do these viruses replicate? More specifically, how do they duplicate their genetic material? Most viruses replicate by transcribing from RNA to RNA, making an RNA strand that is complementary to their genomes. This “opposite” strand is then used to make multiple copies of the viral genome by transcription:

Not all viruses whose genomes consist of RNA replicate by transcribing from RNA to RNA. Some, such as human immunodeficiency viruses (HIVs) and certain rare tumor viruses, make a DNA copy of their genome after infecting a host cell. This DNA copy is then incorporated into the host's genome. Synthesis of DNA from RNA is called **reverse transcription**, and viruses that employ this kind of transcription are called **retroviruses**. Retroviruses rely on the host cell's transcription machinery to make more RNA. This RNA can either be translated to produce viral proteins, or incorporated as the viral genome into new viral particles.

reverse transcription Production of DNA using an RNA template.

retrovirus An RNA virus that contains reverse transcriptase. Its RNA serves as a template for cDNA production, and the cDNA is integrated into a chromosome of the host cell.

14.2 recap

The expression of protein-encoding genes can be broken down into two fundamental steps: transcription and translation. In transcription the DNA code is used to produce mRNA, whose sequence determines the mature mRNA transcript. The mRNA sequence determines the order of amino acids in a polypeptide. Translation is the process by which this information in mRNA is converted into a polypeptide chain.

learning outcomes

You should be able to:

- Describe the central dogma of molecular biology.
- Evaluate gene expression systems to determine whether they adhere to the central dogma of molecular biology.

1. What is the central dogma of molecular biology?
2. Do retroviruses violate the central dogma? Explain.

We will revisit viral genetics in later chapters (in [Key Concepts 16.3](#) and [25.4](#)). In the rest of this chapter we will focus on gene expression in prokaryotes and eukaryotes. Understanding this process is essential for understanding how organisms function at the molecular level and is key to the application of biology to human welfare, in areas such as agriculture and medicine. We'll begin by describing how the information in DNA is transcribed to produce RNA.

14.3 DNA Is Transcribed to Produce RNA

The synthesis of RNA is directed by DNA. The base sequence of one strand of DNA is used as a template for RNA synthesis, so that the RNA made is complementary in sequence to the DNA strand, with the exception that in RNA there is uracil (U) instead of thymine (T) and in RNA the sugar is ribose instead of deoxyribose. It is important to realize that although the RNA made is a mirror image of its DNA template, the RNA has the same sequence as the other, nontemplate strand of DNA. So the information content of DNA is indeed preserved in RNA.

focus your learning

- All RNA polymerases have certain characteristics in common.
- The genetic code allows specific nucleotide sequences in RNA to be translated into specific amino acid sequences in polypeptides.

Transcription—the formation of a specific RNA sequence from a specific DNA sequence—requires several components:

- A DNA template for complementary base pairing; one of the two strands of DNA
- The four ribonucleoside triphosphates ATP, GTP, CTP, and UTP, to act as substrates
- An RNA polymerase enzyme
- Salts and a pH buffer to create an appropriate chemical environment for RNA polymerase (if transcription is performed in a test tube)

Several kinds of RNA are made from DNA templates. The most important from a genetic point of view is mRNA. But transcription also produces tRNA and rRNA, whose roles in protein synthesis will be described below. Like polypeptides, these last two RNAs are encoded by specific genes. Eukaryotes also make many kinds of small RNAs, including small nuclear RNA (snRNA), microRNA (miRNA), and small interfering RNA (siRNA), which are also transcribed. [Table 14.1](#) summarizes some of the RNAs found in eukaryotic cells. We will discuss the roles of miRNA and siRNA in [Chapter 16](#).

table 14.1 Some RNAs in Eukaryotic Cells

RNA type	Location of activity	Role
Ribosomal RNA (rRNA)	Cytoplasm (ribosome)	Binding of mRNA and tRNA and protein synthesis
Messenger RNA (mRNA)	Cytoplasm	Carrier of gene sequence
Transfer RNA (tRNA)	Cytoplasm	Adaptor between mRNA and protein sequences
MicroRNA (miRNA)	Nucleus and cytoplasm	Regulates transcription and translation
Small interfering RNA (siRNA)	Nucleus and cytoplasm	Regulates other RNAs
Small nuclear RNA (snRNA)	Nucleus	Mediates mRNA processing

RNA polymerases share common features

[RNA polymerases](#) from both prokaryotes and eukaryotes catalyze the synthesis of RNA from

the DNA template. There is only one kind of RNA polymerase in bacteria, whereas there are several kinds in eukaryotes; however, they all share a common structure ([Figure 14.3](#)). Like DNA polymerases, RNA polymerases catalyze the addition of nucleotides in a 5'-to-3' direction and are processive; that is, a single enzyme–template binding event results in the polymerization of hundreds of RNA bases. But unlike DNA polymerases (see [Figure 13.11](#)), RNA polymerases *do not require a primer*.

RNA polymerase An enzyme that catalyzes the formation of RNA from a DNA template.

Figure 14.3 RNA Polymerase Interacting with DNA The RNA polymerase enzyme depicted (in green) is from bacteriophage T7, but it is representative of most other RNA polymerases. Note the size relationship between enzyme and DNA. The inset indicates how this enzyme will be represented in the figures that follow.

Transcription occurs in three steps

Transcription can be divided into three distinct processes: (1) [initiation](#), (2) elongation, and (3) termination. Follow these processes in [Figure 14.4](#).

initiation In molecular biology, the beginning of transcription or translation.

Figure 14.4 DNA Is Transcribed to Form RNA DNA is locally unwound by RNA polymerase to serve as a template for RNA synthesis. The RNA transcript is formed and then peels away, allowing the DNA that has already been transcribed to rewind into a double helix. Three distinct processes—initiation, elongation, and termination—

constitute transcription. RNA polymerase is much larger in reality than indicated here, covering about 50 base pairs.

Q: Comparing RNA synthesis with DNA replication, what are the common features?

Animation 14.1 **Transcription** www.Life11e.com/a14.1

INITIATION

Transcription begins when RNA polymerase binds to a special sequence of DNA called a **promoter** (see [Figure 14.4A](#)). Eukaryotic genes generally have one promoter each, whereas in prokaryotes and viruses, several genes often share one promoter. Promoters are important control sequences that “tell” the RNA polymerase two things:

promoter A DNA sequence to which RNA polymerase binds to initiate transcription.

- . Where to start transcription
- . Which strand of DNA to transcribe

A promoter reads in a particular direction, so it orients the RNA polymerase and thus “aims” it at the appropriate strand to use as a template. Part of each promoter is the **initiation site**, where transcription begins. Groups of nucleotides lying “upstream” from the initiation site (5’ on the non-template strand and 3’ on the template strand) help the RNA polymerase bind. Other proteins, which can bind to specific DNA sequences and to RNA polymerase, help direct the polymerase onto the promoter. These proteins, called **sigma factors** in prokaryotes and **transcription factors** in eukaryotes, help determine which specific genes are expressed at a particular time in the cell.

initiation site The place within a promoter where transcription begins.

sigma factor In prokaryotes, a protein that binds to RNA polymerase, allowing the complex to bind to and stimulate the transcription of a specific class of genes (e.g., those involved in sporulation).

transcription factors Proteins that assemble on a eukaryotic chromosome, allowing RNA polymerase II to perform transcription.

Although every gene has a promoter, not all promoters are identical. Some are more effective at transcription initiation than others. Furthermore, there are differences between transcription initiation in prokaryotes and in eukaryotes. We will discuss promoters and their roles in the regulation of gene expression in [Chapter 16](#).

ELONGATION

After RNA polymerase has bound to the promoter, it begins the process of **elongation** (see [Figure 14.4B](#)). DNA unwinds about 10 base pairs at a time and RNA polymerase reads the template strand in the 3’-to-5’ direction. The first nucleotide in the new RNA forms its 5’ end, and subsequent nucleotides complementary to the DNA template are added to its 3’ end. Thus the RNA transcript is antiparallel to the DNA template strand.

elongation (1) In molecular biology, the addition of monomers to make a longer RNA or protein during transcription or translation. (2) Growth of a plant axis or cell primarily in the

longitudinal direction.

You may recall from [Key Concept 13.3](#) that DNA polymerase uses dNTPs (deoxyribonucleoside triphosphates) as substrates, and forms covalent bonds between each incoming dNTP and the 3' end of the growing polynucleotide chain (see [Figure 13.10](#)). Energy released by the removal of two phosphate groups from the dNTP is used to drive the reaction. Similarly, RNA polymerase uses (ribo)nucleoside triphosphates (NTPs) as substrates, removing two phosphate groups from each substrate molecule and using the released energy to drive the polymerization reaction.

Because RNA polymerases do not proofread, transcription errors occur at a rate of one for every 10^4 to 10^5 bases. Because many copies of RNA are made, however, and because they often have only a relatively short life span, these errors are not as potentially harmful as mutations in DNA.

TERMINATION

Just as initiation sites in the DNA template strand specify the starting point for transcription, particular base sequences specify its [termination](#) (see [Figure 14.4C](#)). There are two mechanisms for ending transcription. For some genes, the newly formed transcript folds back on itself and forms internal hydrogen bonds between bases. A loop forms, and this structure causes the transcript to fall away from the DNA template and the RNA polymerase. In other cases, a protein binds to specific sequences on the transcript and causes the RNA to detach from the DNA template.

termination In molecular biology, the end of transcription or translation.

The genetic code specifies which amino acids will be included in the polypeptide

The [genetic code](#) is the informational key by which a sequence of mRNA nucleotides corresponding to a gene is translated into the sequence of amino acids composing the protein expressed by that gene. That is, the genetic code specifies which amino acids will be used to build a protein. You can think of the code as consisting of a series of sequential, non-overlapping, three-letter “words.” The three “letters” represent three adjacent nucleotide bases in the mRNA polynucleotide. Each three-letter “word” is called a [codon](#), and each codon specifies a particular amino acid. Each codon is complementary to the corresponding triplet of bases in the DNA molecule from which it was transcribed. In short, the genetic code relates codons to their specifically encoded amino acids.

genetic code The set of instructions, in the form of nucleotide triplets, that translate a linear sequence of nucleotides in mRNA into a linear sequence of amino acids in a protein.

codon Three nucleotides in messenger RNA that direct the placement of a particular amino acid into a polypeptide chain. (Contrast with anticodon.)

CHARACTERISTICS OF THE CODE

Molecular biologists “broke” the genetic code in the early 1960s. The problem they addressed was perplexing: how could more than 20 “code words” be written with an “alphabet” consisting of only four “letters”? In other words, how could four bases (A, U, G, and C) code for 20 different amino acids?

A triplet code, based on three-letter codons, was considered likely. Since there are only four

letters (A, G, C, and U), a one-letter code clearly could not unambiguously encode 20 amino acids; it could encode only four of them. A two-letter code could have only $4 \times 4 = 16$ unambiguous codons—still not enough. But a triplet code could have $4 \times 4 \times 4 = 64$ codons, more than enough to encode the 20 amino acids.

Marshall W. Nirenberg and J. H. Matthaei, at the U.S. National Institutes of Health, made the first decoding breakthrough in 1961 when they realized that the code would be easier to break if they were working with a very simple, known mRNA sequence rather than with a complex natural mRNA molecule. They set out to synthesize mRNA molecules consisting of just one type of nucleotide base; poly U mRNA, for example, consisted of just uracil nucleotides. Nirenberg and Matthaei's goal was to then identify, through a translation process conducted in a test tube, the polypeptide that the artificial messenger encoded. Their experiment, which is laid out in **Investigating Life: Deciphering the Genetic Code**, led to the identification of the first codons. Other scientists soon identified the rest of the code. This was a major achievement, linking the information in DNA (the gene) to its expression in a protein (the phenotype). The understanding that the amino acids for each protein are spelled out via codons not only led to our understanding of the fundamentals of genetics and mutation, but to investigations into the genetic underpinnings of disease, such as the development of resistance in MRSA described in the opening of this chapter.

Animation 14.2 **Deciphering the Genetic Code** www.Life11e.com/a14.2

The complete genetic code is shown in **Figure 14.5**. Notice that there are many more codons than there are different amino acids in proteins. Proteins are built from just 20 amino acids, but all possible combinations of the four available “letters” (the bases) give 64 (4^3) different three-letter codons. Why are there more codons than amino acids? One reason is that there is more than one codon for almost all amino acids. For example, leucine is represented by six different codons (see **Figure 14.5**). Only methionine and tryptophan are represented by just one codon each. Thus we say that the genetic code is redundant (or degenerate). Also, a few select codons serve functions other than coding for amino acids. AUG, for example, not only codes for methionine but is also the **start codon**, the initiation signal for translation. Three codons (UAA, UAG, UGA) are **stop codons**, or termination signals for translation. When the translation machinery reaches one of these codons, translation stops and the polypeptide is released from the translation complex.

		Second letter					
		U	C	A	G

Deciphering the Genetic

experiment

Original Paper: Nirenberg, M. and H. Matthaei. 1961. The dependence of cell-free protein synthesis in *E. coli* upon naturally occurring or synthetic polyribonucleotides. *Proceedings of the National Academy of Sciences USA* 47: 1588–1602.

Nirenberg and Matthaei used a test tube protein synthesis system to determine the amino acids specified by synthetic mRNAs of known compositions.

HYPOTHESIS ▶ An artificial mRNA containing only one repeating base will direct the synthesis of a protein containing only one repeating amino acid.

METHOD

RESULTS

CONCLUSION ▶ Poly U contains codons for phenylalanine. Poly C contains codons for proline.

work with the data

After the relationship between DNA and proteins was established, genetic evidence pointed to triplets of nucleotides on RNA specifying each amino acid. The race was on to identify which triplet coded for which amino acid. Test tube systems were developed in which cell extracts were made and protein synthesis occurred. It was detected by supplying all 20 amino acids, with one of them being radioactive. Marshall Nirenberg, a scientist at the U.S. National Institutes of Health, and Heinrich Matthaei, a postdoctoral fellow from Germany, made a synthetic RNA consisting of the base uracil only (called poly U, codon UUU) and tested it in 20 tubes. Each test tube was supplied with all 20 amino acids, but in each one a different amino acid was tagged with a radioactive marker. In only one of them was a polypeptide made: a protein consisting of the amino acid phenylalanine bonded repeatedly to itself.

QUESTIONS

1. Poly U, an artificial mRNA, was added to a test tube with all the other components for protein synthesis ("complete system"). Other test tubes differed from the complete system as indicated in the table. Samples were tested for radioactive phenylalanine incorporation, with the results in **Table A**. Explain the results for each of the conditions.

Table A

Condition	Counts/minute (units of radioactivity)
Complete system	29,500
Minus poly U mRNA	70
Minus ribosomes	52
Minus ATP	83
Plus RNase (hydrolyzes RNA)	120
Plus DNase (hydrolyzes DNA)	27,600
Radioactive glycine instead of phenylalanine	33
Mixture of 19 radioactive amino acids minus phenylalanine	276

2. Poly U (red dots) was added to the test tubes at various intervals. Samples were tested for protein synthesis by radioactive amino acid incorporation after various times (and were compared with results of a

control run, in which no RNA was added, indicated by blue dots). The results are shown in the figure below. What do these data show about the dependence of protein synthesis on added RNA?

3. The experiment described in Question 2 was repeated with different amino acids; the results are in **Table B**. Explain these results in terms of the codon specificity of poly U.

Table B

Radioactive amino acid	Counts/minute/mg protein (radioactivity level)
Phenylalanine	38,300
Glycine, alanine, serine, aspartic acid, glutamic acid	33
Leucine, isoleucine, threonine, methionine, arginine, histidine, valine, lysine, tyrosine, proline, tryptophan	276
Cysteine	113

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Don't confuse a *redundant* code with an *ambiguous* code. If the code were ambiguous, a single codon could specify two (or more) different amino acids, and there would be doubt about which amino acid should be incorporated into a growing polypeptide chain. Redundancy in the code simply means there is more than one clear way to say "Put leucine here." The genetic code is not ambiguous: a given amino acid may be encoded by more than one codon, but a codon can code for only one amino acid.

THE GENETIC CODE IS (NEARLY) UNIVERSAL

The same basic genetic code is used by all the species on our planet. Thus the code must be an ancient one that has been maintained intact throughout the evolution of living organisms.

Exceptions are known: for example, the code for ***mitochondrial DNA and chloroplast DNA** differs slightly from that used by prokaryotes and for the nuclear DNA of eukaryotic cells; and in one group of protists, UAA and UAG code for glutamine rather than for stop codons. The significance of these differences is not yet clear. What is clear is that the exceptions are few.

A common genetic code provides a common language for evolution. Natural selection acts on phenotypic variations that result from genetic variation. The genetic code probably originated early in the evolution of life. As we saw in [Chapter 4](#), simulation experiments indicate the plausibility of individual nucleotides and nucleotide polymers arising spontaneously on primeval Earth. The common code also has profound implications for genetic engineering, as we will see in [Chapter 18](#), since it means that the code for a human gene is the same as that for a bacterial gene. It is therefore impressive, but not surprising, that a human gene can be expressed in *E. coli* via laboratory manipulations, since these cells speak the same "molecular language."

The codons illustrated in the Nirenberg and Matthaei experiment in Investigating Life:

Deciphering the Genetic Code are mRNA codons. The base sequence of the DNA strand that is transcribed to produce the mRNA is complementary and antiparallel to these codons. Thus, for example, 3'-AAA-5' in the template DNA strand corresponds to phenylalanine (which is encoded by the mRNA codon 5'-UUU-3').

3'-ACC-5' in the template DNA corresponds to tryptophan (which is encoded by the mRNA codon 5'-UGG-3').

The non-template strand of DNA has the same sequence as the mRNA (but with T's instead of U's), and is often referred to as the "coding strand." By convention, DNA sequences are usually shown beginning with the 5' end of the coding sequence.

You might be thinking that in a long DNA molecule with many protein-coding regions, one strand is the coding strand for all the genes and the other strand is the template strand. In fact, some genes are transcribed from one strand and some genes are transcribed from the other. There is strand switching along a long DNA molecule in terms of the roles of the two strands. So while one strand may not be said to be "the" coding strand for all genes in a particular DNA molecule, for a given gene it is correct to say that one strand is coding and its complementary strand is template.

14.3 recap

Transcription, which is catalyzed by an RNA polymerase, proceeds in three steps: initiation, elongation, and termination. The genetic code relates the information in mRNA (as a linear sequence of codons) to protein (a linear sequence of amino acids).

learning outcomes

You should be able to:

- Describe characteristics of RNA polymerases.
- Justify the need for a triplet code.
- Analyze the biological consequences of a triplet code.

1. Explain why the genetic code has triplets (e.g., AUA) of nucleotides, rather than singlets (e.g., A) or doublets (e.g., AU).
2. Describe the actions of RNA polymerase during transcription.
3. Errors in transcription occur about 100,000 times more often than errors in DNA replication. Why can this higher rate be tolerated in RNA but not in DNA synthesis?

The general features of transcription that we have described were first elucidated in model prokaryotes, such as *E. coli*. Biologists then used the same methods to analyze this process in eukaryotes, and although the basics are the same, there are some notable (and important) differences. We will now turn to a more detailed description of eukaryotic gene expression.

***connect the concepts** As discussed in [Key Concept 12.5](#), some cytoplasmic organelles, notably the mitochondria and chloroplasts, contain small numbers of genes that are remnants of the genomes of the prokaryotes that eventually gave rise to these organelles. The evolutionary process of endo-symbiosis that is responsible for the assimilation of these organelles into eukaryotic cells is discussed in [Key Concept 27.1](#).

14.4 Eukaryotic Pre-mRNA Transcripts Are Processed prior to Translation

Since all organisms share the same genetic code, you might expect the process of gene expression to be the same in eukaryotes as it is in prokaryotes. And basically it is. In the last section, you learned about common features for transcription in all organisms. Our focus here is on the differences. [Table 14.2](#) lists the primary differences between prokaryotic and eukaryotic gene transcription.

table 14.2 Differences between Prokaryotic and Eukaryotic Gene Expression		
Characteristic	Prokaryotes	Eukaryotes
Transcription and translation occurrence	At the same time in the cytoplasm	Transcription in the nucleus, then translation in the cytoplasm
Gene structure	DNA sequence is read in the same order as the amino acid sequence	Noncoding introns within coding sequence
Modification of mRNA after initial transcription but before translation	Usually none	Introns spliced out; 5' end cap and 3' poly A tail added

focus your learning

Eukaryotic mRNA transcripts undergo splicing and end modifications before translation.

In prokaryotes and eukaryotes, the sequence of an mRNA that reaches the ribosome is complementary to the sequence of a gene in the organism's DNA. One way to show this is by the technique of [nucleic acid hybridization](#), shown in [Figure 14.6A](#). This technique involves two steps:

nucleic acid hybridization A technique in which a single-stranded nucleic acid probe is made that is complementary to, and binds to, a target sequence, either DNA or RNA. The resulting double-stranded molecule is a hybrid.

(A) The process of nucleic acid hybridization

(B) Hybridization experiments reveal noncoding introns in eukaryotic genes

Figure 14.6 Nucleic Acid Hybridization and Introns (A) Base pairing permits the detection of a sequence that is complementary to a probe. (B) Hybridization experiments show that there are introns in eukaryotic genes but generally not in prokaryotic genes.

- A sample of chromosomal DNA containing the gene is denatured to break the hydrogen bonds between the base pairs and separate the two strands.
- The single-strand mRNA (called a **probe**) is incubated with the denatured DNA. If the probe has a base sequence complementary to the target DNA, a probe-target double helix forms by hydrogen bonding between the bases. Because the two strands are from different sources, the

resulting double-strand region is called a hybrid.

probe A segment of single-stranded nucleic acid used to identify DNA molecules containing the complementary sequence.

Hybridization experiments can be performed with various combinations of DNA and RNA (RNA as target and DNA as probe; DNA as both target and probe, etc.). In many hybridization experiments, the probe is labeled in some way so that its binding to a specific target sequence can be detected. The double-strand hybrids can also be viewed by electron microscopy.

Noncoding sequences called introns often appear between genes in eukaryotic chromosomes

Differences between prokaryotic and eukaryotic transcription are revealed when mRNA probes from prokaryotes and eukaryotes are incubated with their respective chromosomal DNAs:

In prokaryotes ([Figure 14.6B](#), **top**), there is usually a 1:1 linear complementarity between the base sequence of the mRNA at the ribosome and that of the chromosomal DNA.

In eukaryotes ([Figure 14.6B](#), **bottom**), one or more nonhybridized DNA loops are often observed to extrude out of the mRNA–DNA hybrid, indicating that there are stretches of DNA sequence that do not have a complementary sequence in the mRNA that is translated at the ribosome.

The discovery that some stretches of eukaryotic DNA sequence are excluded from the mRNA that reaches the ribosome for translation initiated the question of whether this “extra” DNA actually gets transcribed. Does transcription “skip” these “extra” sequences, or are they transcribed and then somehow edited out of the mRNA transcript before it arrives at the ribosome? To find out, an experiment can be conducted in which the initial mRNA transcript in the cell nucleus—the **precursor mRNA**, or **pre-mRNA** (see [Figure 14.2](#))—is hybridized with chromosomal DNA. If the pre-mRNA exhibits full, linear, loopfree hybridization with the template DNA, we may conclude that the noncoding, intervening regions of DNA, known as **introns**, do get transcribed but are then spliced out of the pre-mRNA in the nucleus. The experiment demonstrates that only the coding sequences (**exons**) remain in the mRNA that reaches the ribosome. The step of editing out the introns is known as **RNA processing** and is shown in [Figure 14.7](#).

pre-mRNA (precursor mRNA) Initial gene transcript before it is modified to produce functional mRNA. Also known as the primary transcript.

intron Portion of a gene within the coding region that is transcribed into pre-mRNA but is spliced out prior to translation. (Contrast with exon.)

exon A portion of a DNA molecule, in eukaryotes, that codes for part of a polypeptide. (Contrast with intron.)

RNA processing Modification of RNA primary transcripts, for example splicing out of introns.

Figure 14.7 Transcription of a Eukaryotic Gene The β -globin gene diagrammed here is about 1,600 base pairs (bp) long. The three exons—the protein-coding sequences—contain codons for 146 amino acids plus a stop codon. The two introns—noncoding sequences of DNA containing almost 1,000 bp among them—are initially transcribed but are spliced out of the pre-mRNA transcript.

Introns *interrupt, but do not scramble*, the DNA sequence of a gene. The base sequences of the exons in the template strand, if joined and taken in order, form a continuous sequence that is complementary to that of the mature mRNA. In some cases, the separated exons often encode different functional regions, or **domains**, of the protein. For example, the globin polypeptides that make up hemoglobin each have two domains: one for binding to a nonprotein pigment called heme, and another for binding to the other globin subunits. These two domains are encoded by different exons in the globin genes. Most (but not all) eukaryotic genes contain introns, and in rare cases, introns are also found in prokaryotes. The largest human gene encodes a muscle protein called titin; it has 363 exons, which together code for 38,138 amino acids.

domain (1) An independent structural element within a protein. Encoded by recognizable nucleotide sequences, a domain often folds separately from the rest of the protein. Similar domains can appear in a variety of different proteins across phylogenetic groups (e.g., “homeobox domain,” “calcium-binding domain”). (2) In phylogenetics, the three monophyletic branches of life (Bacteria, Archaea, and Eukarya).

Pre-mRNA processing prepares the mRNA transcript for translation

The transcript of a eukaryotic gene is modified in several ways before it leaves the nucleus: both ends of the pre-mRNA are modified, and the introns are removed.

MODIFICATION AT BOTH ENDS

Two steps in the processing of pre-mRNA take place in the nucleus, one at each end of the molecule (**Figure 14.8**):

Figure 14.8 Processing the Ends of Eukaryotic Pre-mRNA Modifications at each end of the pre-mRNA transcript—the 5' cap and the poly A tail—are important for mRNA function.

- A **5' cap** is added to the 5' end of the pre-mRNA as it is transcribed. The 5' cap, which is a chemically modified molecule of guanosine triphosphate (GTP), facilitates the binding of mRNA to the ribosome for translation, and it protects the mRNA from being digested by ribonucleases that break down RNAs.
- A **poly A tail** is added to the 3' end of the pre-mRNA at the end of transcription. Transcription ends downstream of the termination codon in DNA. In eukaryotes there is usually a “polyadenylation” sequence (AAUAAA) near the 3' end of the pre-mRNA, after the last codon. This sequence acts as a signal for an enzyme to cut the pre-mRNA. Immediately after this cleavage, another enzyme adds 100 to 300 adenine nucleotides (the poly A tail) to the 3' end of the pre-mRNA. This tail helps in the export of mature mRNA from the nucleus and is important for mRNA stability.

5' cap (5 prime) Methylated guanine nucleotide bonded to the 5' end of eukaryotic mRNA.

poly A tail A long sequence of adenine nucleotides (50–250) added after transcription to the 3' end of most eukaryotic mRNAs.

SPLICING TO REMOVE INTRONS

Within the nucleus, introns are removed from eukaryotic pre-mRNA. If these RNA sequences were not removed, a very different amino acid sequence, and possibly a nonfunctional protein, would result. A process called **RNA splicing** removes the introns and splices the exons together. You can follow the steps of this important process in **Figure 14.9**.

RNA splicing The last stage of RNA processing in eukaryotes, in which the transcripts of introns are excised through the action of small nuclear ribonucleoprotein particles (snRNP).

Figure 14.9 RNA Splicing The binding of snRNPs to consensus sequences bordering the introns on the pre-mRNA results in a series of proteins binding and cutting the pre-mRNA with great precision.

▶ Animation 14.3 **RNA Splicing** www.Life11e.com/a14.3

Molecular studies of human genetic diseases have provided insights into RNA splicing. For example, people with the genetic disease beta thalassemia have a defect in the production of one of the hemoglobin subunits. These people suffer from severe anemia because they have an inadequate supply of red blood cells. In some cases, the genetic mutation that causes the disease occurs at an intron consensus sequence, where the splicing machinery binds to the RNA (see Figure 14.9, step 1) in the β -globin gene. Consequently, β -globin pre-mRNA cannot be spliced correctly, and β -globin mRNA that encodes a nonfunctional polypeptide is made. This finding offers another example of how biologists can use mutations to elucidate biological processes.

After processing is completed in the nucleus, the mature mRNA moves out into the cytoplasm through the nuclear pores. A protein bound to the 5' nucleotide cap during processing is recognized by a receptor at the nuclear pore. Together, these proteins lead the mRNA through the pore. Unprocessed or incompletely processed pre-mRNAs remain in the nucleus.

14.4 recap

Most eukaryotic genes contain noncoding sequences called introns, which are removed from the pre-mRNA transcript in the nucleus. The mature mRNA transcript is then exported

through a nuclear pore to ribosomes in the cytoplasm, where translation takes place.

learning outcomes

You should be able to:

- Describe the mRNA processing steps in eukaryotes.
 - Predict the outcome of a defect in mRNA processing in a eukaryotic cell.
 - Compare the features of a eukaryotic gene, noting introns, exons, and signals, with its mature mRNA transcript.
-
1. How and why is the pre-mRNA transcript modified at the 5' and 3' ends during mRNA processing?
 2. Outline the steps involved in RNA splicing. What are the consequences if it does not happen correctly?
 3. A gene that is 1,440 base pairs long codes for a polypeptide that is 192 amino acids long. Discuss the discrepancy.
-

Transcription and posttranscriptional events produce an mRNA that is ready to be translated into a sequence of amino acids in a polypeptide. We will turn now to the events of translation.

14.5 The Information in mRNA Is Translated into Proteins

When two languages are different (e.g., English and German) and you want to know what a word in one language means in the other, you may need to consult a foreign-language dictionary or an online translator. Likewise, a “translator” is required to convert the information in mRNA (a language composed of a sequence of nucleotides) into the language of protein (consisting of a sequence of amino acids). In biology, that translator is a special kind of RNA molecule called transfer RNA (tRNA). To ensure accurate translation—that is, to ensure that the protein made is the one specified by the mRNA—the tRNAs must (1) read each codon correctly, and (2) fetch the amino acids corresponding to each codon and deliver them to the ribosome.

focus your learning

Ribosomes catalyze the translation of mRNA into polypeptide chains according to the following sequence of events: initiation, elongation, and termination.

Polysomes allow simultaneous synthesis of multiple polypeptide chains from the same mRNA molecule.

Once the tRNAs “decode” the mRNA and deliver the appropriate amino acids, components of the ribosome catalyze the formation of peptide bonds between amino acids. Let’s now look at how the tRNAs read codons and get the appropriate amino acids into the ribosome.

▶ Animation 14.4 Translation www.Life11e.com/a14.4

A transfer RNA carries a specific amino acid and binds to a specific mRNA codon

There is at least one specific tRNA molecule for each of the 20 amino acids. Each tRNA has three functions that are fulfilled by its structure and base sequence ([Figure 14.10](#)):

Figure 14.10 Transfer RNA The stem and loop structure of a tRNA molecule is well

suited to its functions: binding to amino acids, associating with mRNA molecules, and interacting with ribosomes.

- . *tRNAs bind to particular amino acids.* Each tRNA binds to a specific enzyme that attaches it to only 1 of the 20 amino acids. The covalent attachment to an amino acid takes place at the 3' end of the tRNA. When it is carrying an amino acid, the tRNA is said to be "charged."
- . *tRNAs bind to mRNA.* At about the midpoint on the tRNA polynucleotide chain there is a triplet of bases called the **anticodon**, which is complementary to the mRNA codon for the particular amino acid that the tRNA carries. For example, the mRNA codon for arginine is 5'-CGG-3', and the complementary tRNA anticodon is 3'-GCC-5'. Like the two strands of DNA, the codon and anticodon bind together via noncovalent hydrogen bonds.
- . *tRNAs interact with ribosomes.* The ribosome has several sites on its surface that just fit the three-dimensional structure of a tRNA molecule. Interaction between the ribosome and the tRNA is noncovalent.

anticodon The three nucleotides in transfer RNA that pair with a complementary triplet (a codon) in messenger RNA.

Recall that 61 different codons encode the 20 amino acids in proteins (see [Figure 14.5](#)). Does this mean that the cell must produce 61 different tRNA species, each with a different anticodon? No. The cell gets by with about two-thirds of that number of tRNA species because the specificity for the base at the 3' end of the codon (and the 5' end of the anticodon) is not always strictly observed. This phenomenon is called wobble, and it is possible because in some cases unusual or modified nucleotide bases occur in the 5' position of the anticodon. One such unusual base is inosine (I), which can pair with A, C, and U. For example, the presence of inosine in the tRNA with the anticodon 3'-CGI-5' allows it to recognize and bind to three of the alanine codons: GCA, GCC, and GCU. Wobble occurs in some matches but not in others; of most importance, it does not allow the genetic code to be ambiguous. That is, *each mRNA codon binds to just one tRNA species, carrying a specific amino acid.*

Each tRNA is specifically attached to an amino acid

The charging of each tRNA with its correct amino acid is achieved by a family of enzymes known as aminoacyl-tRNA synthetases. Each enzyme is specific for one amino acid and for its corresponding tRNA. The reaction uses ATP, forming a high-energy bond between the amino acid and the tRNAs ([Figure 14.11](#)). The energy in this bond is later used in the formation of peptide bonds between amino acids in a growing polypeptide chain.

Figure 14.11 Charging a tRNA Molecule The aminoacyl-tRNA synthetase activates a specific amino acid and charges a specific tRNA with that amino acid.

The specificity between the tRNA and its corresponding amino acid is essential. These reactions, for example, are highly specific:

A clever experiment by Seymour Benzer and his colleagues at Purdue University demonstrated the importance of this specificity. They took the cys-tRNA molecule and chemically modified the cysteine, converting it into alanine. Which component—the amino acid or the tRNA—would be recognized when this hybrid charged tRNA was put into a protein synthesizing system? The answer was the tRNA. Everywhere in the synthesized protein where cysteine was supposed to be, alanine appeared instead. The cysteine-specific tRNA had delivered its cargo (alanine) to every mRNA codon for cysteine. This experiment showed that the protein synthesis machinery recognizes the anticodon of the charged tRNA, not the amino acid attached to it.

The ribosome is the workbench for translation

The ribosome is the molecular workbench where the task of translation is accomplished. Its structure enables it to hold mRNA and charged tRNAs in the correct positions, thus allowing a polypeptide chain to be assembled efficiently. A given ribosome does not specifically produce just one kind of protein. A ribosome can use any mRNA and all species of charged tRNAs, and thus can be used to make many different polypeptide products. Ribosomes can be used over and over again, and there are thousands of them in a typical cell.

Although ribosomes are small relative to other cellular structures, their mass of several million daltons makes them large in comparison with charged tRNAs. Each ribosome consists of two subunits, a large one and a small one ([Figure 14.12](#)). The two subunits and several dozen other

molecules interact noncovalently. In fact, when hydrophobic interactions between the proteins and RNAs are disrupted, the ribosome falls apart. The two subunits separate and all the RNAs and proteins separate from one another. If the disrupting agent is removed, the complex structure self-assembles perfectly! This is amazing: think of throwing the pieces of a jigsaw puzzle up in the air and having them fit together when they land. The ribosome reflects the high specificity of molecular machines in a cell composed of many molecules.

Figure 14.12 Ribosome Structure Each ribosome consists of a large and a small subunit. The subunits remain separate when they are not being used for protein synthesis.

Q: The ribosome consists of several dozen proteins and several RNA molecules, held together noncovalently. What are the chemical forces involved? How can these forces be disrupted and the molecules separated from one another?

In eukaryotes, the large subunit consists of three different molecules of ribosomal RNA (rRNA) and 49 different protein molecules, arranged in a precise configuration. The small subunit consists of 1 rRNA molecule and 33 different protein molecules. The ribosomes of prokaryotes are somewhat smaller than those of eukaryotes, and their ribosomal proteins and RNAs are different. Mitochondria and chloroplasts also contain ribosomes, some of which are similar to those of prokaryotes (see [Chapter 5](#)).

There are three sites to which a tRNA can bind on the large subunit of the ribosome, designated A, P, and E (see [Figure 14.12](#)). The mRNA and ribosome move in relation to one another, and as they do so, a charged tRNA traverses these three sites in order:

- . The *A (aminoacyl-tRNA) site* is where the charged tRNA anticodon binds to the mRNA codon, thus lining up the correct amino acid to be added to the growing polypeptide chain.
- . The *P (peptidyl-tRNA) site* is where the tRNA adds its amino acid to the polypeptide chain.
- . The *E (exit) site* is where the tRNA, having given up its amino acid, resides before being released from the ribosome and going back to the cytosol to pick up another amino acid and begin the process again.

The ribosome has a fidelity function that ensures that the mRNA–tRNA interactions are accurate; that is, that a charged tRNA with the correct anticodon (e.g., 3'-UAC-5') binds to the appropriate codon in mRNA (e.g., 5'-AUG-3'). When proper binding occurs, hydrogen bonds form between the paired bases. The rRNA of the small ribosomal subunit plays a role in

validating the three-base-pair match. If hydrogen bonds have not formed between all three base pairs, the tRNA must be the wrong one for that mRNA codon, and the incorrect tRNA is ejected from the ribosome.

Translation takes place in three steps

Translation is the process by which the information in mRNA (derived from DNA) is used to specify and link a specific sequence of amino acids, producing a polypeptide. Like transcription, translation occurs in three steps: initiation, elongation, and termination.

INITIATION

The translation of mRNA begins with the formation of an [initiation complex](#), which consists of a charged tRNA and a small ribosomal subunit, both bound to the mRNA ([Figure 14.13](#)).

initiation complex In protein translation, a combination of a small ribosomal subunit, an mRNA molecule, and the tRNA charged with the first amino acid coded for by the mRNA; formed at the onset of translation.

Figure 14.13 The Initiation of Translation Translation begins with the formation of an initiation complex. In prokaryotes, the small ribosomal subunit binds to the Shine–Dalgarno sequence to begin the process, whereas in eukaryotes it binds to the 5' cap.

In prokaryotes, the rRNA of the small ribosomal subunit first binds to a complementary ribosome binding site (AGGAGG; known as the Shine–Dalgarno sequence) on the mRNA. This sequence is less than 10 bases upstream of the actual start codon but lines up the start codon so that it is adjacent to the P site of the large subunit:

mRNA 5' A G G A G G (start codon) 3'

rRNA 3' U C C U C C (P site) 5'

Eukaryotes load the mRNA onto the ribosome somewhat differently: the small ribosomal subunit binds to the 5' cap on the mRNA and then moves along the mRNA until it reaches the start codon.

Recall that the mRNA start codon in the genetic code is AUG (see [Figure 14.5](#)). The anticodon (UAC) of a methionine-charged tRNA binds to this start codon by complementary base pairing to complete the initiation complex. Thus the first amino acid in a polypeptide chain is always methionine. However, not all mature proteins have methionine as their N-terminal amino acid. In many cases, the initial methionine is removed by an enzyme after translation.

After the methionine-charged tRNA has bound to the mRNA, the large subunit of the ribosome joins the complex. The methionine-charged tRNA now lies in the P site of the ribosome, and the A site is aligned with the second mRNA codon. These ingredients—mRNA, two ribosomal subunits, and methionine-charged tRNA—are assembled by a group of proteins called initiation factors.

ELONGATION

A charged tRNA whose anticodon is complementary to the second codon of the mRNA now enters the open A site of the large ribosomal subunit ([Figure 14.14](#)). The large subunit then catalyzes two reactions:

Elongation

- 1 Codon recognition:** The anticodon of an incoming tRNA binds to the codon at the A site.

- 2 Peptide bond formation:** Pro is linked to Met by peptidyl transferase activity of the large subunit.

- 3 Elongation:** Free tRNA is moved to the E site, and then released, as the ribosome shifts by one codon, so that the growing polypeptide chain moves to the P site.

- 4 The process repeats.**

Figure 14.14 The Elongation of Translation The polypeptide chain elongates as the mRNA is translated.

- . It breaks the bond between the tRNA and its amino acid in the P site.
- . It catalyzes the formation of a peptide bond between the amino acid that has just been released from the P site and the one attached to the tRNA in the A site.

Because the large ribosomal subunit performs these two actions, it is said to have **peptidyl transferase** activity. In this way, methionine (the amino acid in the P site) becomes the N terminus of the new protein. The second amino acid is now bound to methionine but remains attached to its tRNA at the A site.

peptidyl transferase A catalytic function of the large ribosomal subunit that consists of two reactions: breaking the bond between an amino acid and its tRNA in the P site, and forming a peptide bond between that amino acid and the amino acid attached to the tRNA in the A site.

How does the large ribosomal subunit catalyze peptide bond formation? Harry Noller and his colleagues at the University of California at Santa Cruz did a series of experiments and found that:

if they removed almost all of the proteins from the large subunit, it still catalyzed peptide bond formation.

if the rRNA was extensively modified, peptidyl transferase activity was destroyed.

The experiment showed that *rRNA is the catalyst*. The purification and crystallization of ribosomes has allowed scientists to examine ribosome structure in detail, and the catalytic role of rRNA in peptidyl transferase activity has been confirmed. These findings support the hypothesis that RNA, and ***catalytic RNA** in particular, evolved before DNA.

After the first tRNA releases its methionine, it moves to the E site and is then dissociated from the ribosome, returning to the cytosol to become charged with another methionine. The second tRNA, now bearing a dipeptide (a two-amino acid chain), is shifted to the P site as the ribosome moves one codon along the mRNA in the 5'-to-3' direction. The elongation process continues, and the polypeptide chain grows, as these steps are repeated. Follow the process in [Figure 14.14](#). All these steps are assisted by ribosomal proteins called elongation factors.

TERMINATION

The elongation cycle ends, and translation is terminated, when a stop codon—UAA, UAG, or UGA—enters the A site ([Figure 14.15](#)). Stop codons do not correspond with any amino acids, nor do they bind any tRNAs. Rather, they bind a protein release factor, which allows hydrolysis of the bond between the polypeptide chain and the tRNA in the P site. The newly completed polypeptide thereupon separates from the ribosome. Its C terminus is the last amino acid to join the chain. Its N terminus, at least initially, is methionine, as a consequence of the AUG start codon. In its amino acid sequence, it contains information specifying its conformation, as well as its ultimate cellular destination.

Figure 14.15 The Termination of Translation Translation terminates when the A site of the ribosome encounters a stop codon on the mRNA.

Q: What happens if there is not a stop codon?

[Table 14.3](#) lists the nucleic acid signals for initiation and termination of transcription and translation.

table 14.3 Signals that Start and Stop Transcription and Translation		
	Transcription	Translation
Initiation	Promoter DNA	AUG start codon in the mRNA
Termination	Terminator DNA	UAA, UAG, or UGA in the mRNA

Polysome formation increases the rate of protein synthesis

Several ribosomes can work simultaneously at translating a single mRNA molecule, producing multiple polypeptides at the same time. As soon as the first ribosome has moved far enough from the site of translation initiation, a second initiation complex can form, then a third, and so on. An assemblage consisting of a strand of mRNA with its beadlike ribosomes and their growing polypeptide chains is called a [polyribosome](#), or **polysome** ([Figure 14.16](#)). Cells that are actively synthesizing proteins contain large numbers of polysomes and few free ribosomes or ribosomal subunits.

polyribosome (polysome) A complex consisting of a threadlike molecule of messenger RNA and several (or many) ribosomes. The ribosomes move along the mRNA, synthesizing polypeptide chains as they proceed.

Figure 14.16 A Polysome (A) A polysome consists of multiple ribosomes and their growing polypeptide chains moving along an mRNA molecule. **(B)** An electron micrograph of a polysome

14.5 recap

A key step in protein synthesis is the attachment of an amino acid to its proper tRNA, which is facilitated by a family of specific activating enzymes called aminoacyl-tRNA synthetases. Translation of the genetic information from mRNA into protein occurs at the ribosome in three stages: initiation, elongation, and termination. Multiple ribosomes may act on a single mRNA to make multiple copies of the protein that it encodes.

learning outcomes

You should be able to:

- Describe the process of translation.
- Translate a sequence of DNA into a peptide.
- Explain the biological significance of polysomes.

1. What are the roles of rRNA molecules in the ribosome?
2. Given the DNA sequence: 5'-ATGCCCGGGTTAAGAWTTTAAATGA-3',
 - a. write out the sequence of the complementary DNA strand.
 - b. indicate which strand is used as a template for transcription (and how you know this).
 - c. write out the sequence of the transcribed mRNA, and provide the amino acid sequence of the translated peptide.
3. What are the structure and significance of a polysome?

The polypeptide chain that is released from the ribosome is not necessarily a functional protein. Let's look at some of the post-translational changes that can affect the fate and function of a polypeptide.

***connect the concepts** As discussed in [Key Concept 4.3](#), the folded, three-dimensional surface of an RNA molecule can be just as specific as that of a protein, and may thus take on a catalytic function. The "RNA world" hypothesis, which proposed that RNA serves as a catalyst for its own replication, was boosted by the discovery of ribozymes, catalytic RNAs that can speed up biological reactions, including those that involve their own nucleotides.

14.6 Polypeptides Can Be Modified and Transported during or after Translation

The site of a polypeptide's function may be far away from its point of synthesis in the cytoplasm. This is especially true for eukaryotes. The polypeptide may be moved into an organelle, or even out of the cell. In addition, polypeptides are often modified by the addition of new chemical groups that have functional significance. In this section we examine these posttranslational aspects of protein synthesis.

focus your learning

Direct transport of a protein within a cell or its export out of a cell can be specified by signal sequences attached to the protein.

Posttranslational modifications of proteins can involve proteolytic cleavage, glycosylation, phosphorylation, and other chemical modifications.

How are proteins directed to their cellular destinations?

As a polypeptide chain emerges from the ribosome it may simply fold into its three-dimensional shape and perform its cellular role locally in the cytosol. However, if a newly formed polypeptide is meant to do its work elsewhere, a **signal sequence** (or **signal peptide**)—a short stretch of amino acids attached to the polypeptide—will tell the polypeptide where in the cell it belongs. Proteins destined for different locations have different signals.

signal sequence The sequence within a protein that directs the protein to a particular organelle.

Protein synthesis always begins on free ribosomes, and the “default” location for a protein is the cytosol. In the absence of a signal sequence, the protein will remain in the same cellular compartment in which it was synthesized. Some proteins contain signal sequences that “target” them to the nucleus, mitochondria, plastids, or peroxisomes (**Figure 14.17**). A signal sequence binds to a specific receptor protein at the surface of the organelle. Once it has bound, the targeted protein moves into the organelle. For example, here is a nuclear localization signal (NLS):

Figure 14.17 Destinations for Newly Translated Polypeptides in a Eukaryotic Cell Signal sequences on newly synthesized polypeptides bind to specific receptor proteins on the outer membranes of the organelles to which they are “addressed.” Once the protein has bound to it, the receptor forms a channel in the membrane, and the protein enters the organelle.

Q: What happens to a protein that has no amino acid sequence “address”?

-Pro-Pro-Lys-Lys-Lys-Arg-Lys-Val-

How do we know this signal sequence directs the protein to the nucleus? The function of this NLS peptide was established using experiments like the one illustrated in [Figure 14.18](#). Proteins were made in the laboratory with or without the peptide, and then tested by injecting them into cells. Only proteins with the NLS were found in the nucleus.

Figure 14.18 Testing the Signal

Original Paper: Dingwall, C. et al. 1988. The nucleoplasmin nuclear location sequence is larger and more complex than that of SV-40 large T antigen. *Journal of Cell Biology* 107: 841–849.

A. Richardson and his colleagues performed a series of experiments to test whether the nuclear localization signal (NLS) is all that is needed to direct a protein to the nucleus.

HYPOTHESIS ▶ An NLS is necessary for import of a protein into the nucleus.

METHOD

RESULTS

Injected protein:

Nucleoplasmin, a nuclear protein, with the NLS

Nucleoplasmin with the NLS removed

Pyruvate kinase, a cytoplasmic protein without the NLS

Pyruvate kinase, with attached NLS

CONCLUSION ▶ The NLS is essential for nuclear protein import and is sufficient to direct a normally cytoplasmic protein to the nucleus.

If a polypeptide carries a signal of about 20 hydrophobic amino acids at its N terminus, it will be directed to the rough endoplasmic reticulum (RER) for further processing (see [Figure 14.17](#)). Note that this is not a specific sequence of amino acids, just a generally hydrophobic sequence at the N terminus that is first translated. Translation will pause, and the ribosome will bind to a receptor at the RER membrane. Once the polypeptide–ribosome complex is bound, translation will resume, and as elongation continues, the protein will traverse the RER membrane. Such proteins may be retained in the lumen (the inside of the RER) or in membrane of the RER, or they may move elsewhere within the endomembrane system (Golgi apparatus, lysosomes, and cell membrane). If the proteins lack specific signals or modifications (see below) that specify destinations within the endomembrane system, they are usually secreted from the cell via vesicles that fuse with the cell membrane.

The importance of signals is shown by Inclusion-cell (I-cell) disease, an inherited disease that causes death in early childhood. People with this disease have a mutation in the gene encoding a Golgi enzyme that adds specific sugars to proteins destined for the lysosomes. These sugars act like signal sequences; without them, enzymes that are essential for the hydrolysis of various macromolecules cannot reach the lysosomes, where the enzymes are normally active. Without these enzymes, the macromolecules accumulate in the lysosomes, and this lack of cellular recycling has drastic effects, resulting in early death.

Mitochondria and chloroplasts make some of their own proteins and import others

As you saw in [Chapter 5](#), mitochondria and chloroplasts are semi-autonomous organelles, each having a small amount of DNA. Both organelles contain the entire protein synthesis machinery, including a specific RNA polymerase, and their own specialized ribosomes that differ from the ones in the cytoplasm. The genetic coding capacity of the organelle DNA is small, however:

Mitochondrial DNA encodes mitochondrial rRNAs, a few tRNAs, and 12 to 20 proteins, most of them involved in the electron transport chain.

Chloroplast DNA encodes chloroplast rRNAs, some tRNAs, and about 40 proteins, many of which are involved in photosynthesis.

These organelles contain dozens more proteins, all of which are imported from the nuclear–cytoplasm protein synthesis system. In some cases (e.g., rubisco in the chloroplast) an organelle protein has several subunits, some of which are made locally inside the organelle and others of which are imported from the nucleus–cytoplasm system. As you can imagine, putting this together requires coordination between the two protein synthesis systems.

Many proteins are modified after translation

The amino acid sequences of most mature proteins are not identical to those in the polypeptide chains that are translated from mRNA on the ribosomes, because polypeptides are often modified in any of several ways after translation ([Figure 14.19](#)). These modifications are essential to the final functioning of the protein:

Figure 14.19 Posttranslational Modifications of Proteins Most polypeptides must be modified after translation in order to become functional proteins.

Proteolysis is the cutting of a polypeptide chain, a reaction catalyzed by enzymes called proteases (also called peptidases or proteinases). Cleavage of the signal sequence from the growing polypeptide chain in the RER is an example of proteolysis (see [Figure 14.17](#)); the protein might move back out of the RER through the membrane channel if the signal sequence were not cut off. Some proteins are actually made from polyproteins (long polypeptides) that are cut into final products by proteases. These proteases are essential to some viruses, including human immunodeficiency viruses (HIVs), because the large viral polyprotein cannot fold properly unless it is cut. Certain drugs used to treat acquired immune deficiency syndrome (AIDS) work by inhibiting the HIV protease, thereby preventing the formation of proteins needed for viral reproduction.

Glycosylation is the addition of sugars to proteins to form glycoproteins. In both the RER and the Golgi apparatus, resident enzymes catalyze the addition of various sugars or short sugar chains to certain amino acid R groups on proteins. One such type of “sugar coating” is essential for directing proteins to lysosomes, as mentioned above. Other types are important in the conformation of proteins and their recognition functions at the cell surface (see [Key Concept 6.2](#)). Other attached sugars help stabilize extracellular proteins, or proteins stored in

vacuoles in plant seeds.

Phosphorylation is the addition of phosphate groups to proteins, and is catalyzed by protein kinases. The charged phosphate groups change the conformation of a protein, often exposing the active site of an enzyme or the binding site for another protein. We have seen the important role of phosphorylation in cell signaling (see [Chapter 7](#)) and the cell cycle (see [Chapter 11](#)).

proteolysis [protein + Gk. *lysis*: break apart] An enzymatic digestion of a protein or polypeptide.

glycosylation The addition of carbohydrates to another type of molecule, such as a protein.

phosphorylation Addition of a phosphate group.

14.6 recap

Signal sequences in polypeptides direct them to their appropriate destinations inside or outside the cell. Many polypeptides are modified after translation.

learning outcomes

You should be able to:

- Outline the steps by which a newly synthesized protein is moved into the nucleus or exported outside of the cell.
- Justify the claim that posttranslational modification of a protein is ultimately directed by the DNA sequence of the gene encoding the protein.

1. How do signal sequences determine where a protein will go after it is made?
2. The genetic code determines the amino acid sequence of a protein. Is there a “code” that determines posttranslational modifications such as phosphorylation or glycosylation? How might this relate to the genetic code?

All of the processes we have just described result in a functional protein, but only if the amino acid sequence of that protein is correct. If the sequence is not correct, cellular dysfunction may result. Changes in the DNA—mutations—are a major source of errors in amino acid sequences. This is the subject of the next chapter.

investigatinglife

QA How does knowledge of the genetic code help us understand the actions of some antibiotics?

MRSA can be treated if detected early. Sequencing the DNA of the bacteria can be used to detect mutations and predict the severity of the infection. Antibiotics such as tetracyclines, which target bacterial protein synthesis, are effective in some strains. Tetracyclines kill bacteria by interrupting translation, binding to the small subunit of bacterial ribosomes so that charged tRNA cannot bind to the A site on the ribosome. Tetracyclines do not kill eukaryotic cells, because eukaryotic ribosomes have different proteins and RNAs that do not offer a binding site for tetracyclines.

Whether tetracyclines will continue to offer a viable treatment for MRSA, however, is in doubt. Some strains of MRSA are already resistant to tetracyclines, having acquired genes that convey resistance through bacterial conjugation. The DNA of *S. aureus* has been altered through acquisition of genes from a plasmid so important that it has been given its own name, the resistome. As with methicillin resistance, the alleles of the resistome encode a ribosomal protein with an altered amino acid sequence that consequently does not bind the antibiotic.

Can you think of other ways to target protein synthesis in MRSA?

Future directions

While the expression of protein-coding genes has been well worked out, recent analyses of eukaryotic genomes show that a lot of transcription remains unaccounted for. International cooperation among laboratories in huge projects such as ENCODE (Encyclopedia of DNA Elements) has revealed, for example, that up to 70 percent of human DNA is transcribed at some point in some cells. With only 2 to 3 percent of DNA consisting of protein-coding genes, the question immediately arises as to what purpose the rest of the RNAs serve. A small fraction are tRNAs and rRNAs, and you will see in [Chapter 16](#) that some of these noncoding RNAs are small (< 200 nucleotides) and have roles in regulating the expression of protein-coding genes. The roles of the longer RNAs (> 200 nucleotides) are much less clear. In humans, over 25,000 of the longer RNAs have been identified. They have much in common with mRNAs: they are transcribed using the same RNA polymerase, undergoing poly A addition, capping at the 5' and 3' ends, and splicing. However, the longer RNAs are not as long as mRNAs and are not translated at the ribosome. Some never leave the nucleus, where they may be involved in pre-mRNA events such as transcription and splicing. Others actually arrive at the ribosome, where they may regulate the translation of particular mRNAs. These longer untranslated RNAs are found in many organisms, indicating that they must have important roles that have been selected for in evolution.

▶ 14.1 Genes Code for Proteins

- Experiments on metabolic enzymes in the bread mold *Neurospora* led to the [one-gene, one-enzyme hypothesis](#). We now know that there is a [one-gene, one-polypeptide relationship](#). **Review Figure 14.1**

one-gene, one-enzyme hypothesis See one gene—one polypeptide.
one-gene, one-polypeptide relationship See one gene—one polypeptide.

▶ 14.2 Information Flows from Genes to Proteins

- The [central dogma](#) of molecular biology states that DNA encodes RNA, and RNA encodes proteins. Proteins do not encode proteins, RNA, or DNA.

central dogma The premise that information flows from DNA to RNA to polypeptide (protein).

- The process by which the information in DNA is copied to RNA is called transcription. The process by which a protein is built from the information in RNA is called [translation](#). **Review Focus: Key Figure 14.2, Activity 14.1**

translation The synthesis of a protein (polypeptide). Takes place on ribosomes, using the information encoded in messenger RNA.

- A product of transcription is [messenger RNA \(mRNA\)](#). [Transfer RNAs \(tRNAs\)](#) translate the genetic information in the mRNA into a corresponding sequence of amino acids to produce a polypeptide.

messenger RNA (mRNA) Transcript of a region of one of the strands of DNA; carries information (as a sequence of codons) for the synthesis of one or more proteins.

transfer RNA (tRNA) A family of folded RNA molecules. Each tRNA carries a specific amino acid and anticodon that will pair with the complementary codon in mRNA during translation.

- Certain RNA viruses present exceptions to the central dogma. For example, [retroviruses](#) synthesize DNA from RNA in a process called [reverse transcription](#).

retrovirus An RNA virus that contains reverse transcriptase. Its RNA serves as a template for cDNA production, and the cDNA is integrated into a chromosome of the host cell.

reverse transcription Production of DNA using an RNA template.

▶ 14.3 DNA Is Transcribed to Produce RNA

- In a given gene, only one of the two strands of DNA (the template strand) acts as a

template for transcription. [RNA polymerase](#) is the catalyst for transcription.

RNA polymerase An enzyme that catalyzes the formation of RNA from a DNA template.

- RNA transcription from DNA proceeds in three steps: [initiation](#), [elongation](#), and [termination](#). [Review Figure 14.4, Animation 14.1](#)

initiation In molecular biology, the beginning of transcription or translation.

termination In molecular biology, the end of transcription or translation.

- Initiation requires a [promoter](#), to which RNA polymerase binds. Part of each promoter is the [initiation site](#), where transcription begins.

promoter A DNA sequence to which RNA polymerase binds to initiate transcription.

initiation site The place within a promoter where transcription begins.

- Elongation of the RNA molecule proceeds from the 5' to 3' end.
- Particular base sequences specify termination, at which point transcription ends and the RNA transcript separates from the DNA template.
- The [genetic code](#) is a “language” of triplets of mRNA nucleotide bases ([codons](#)) corresponding to 20 specific amino acids; there are **start** and [stop codons](#) as well. The code is redundant (an amino acid may be represented by more than one codon) but not ambiguous (no single codon represents more than one amino acid). [Review Investigating Life: Deciphering the Genetic Code, Figure 14.5, Animation 14.2, Activity 14.2](#)

genetic code The set of instructions, in the form of nucleotide triplets, that translate a linear sequence of nucleotides in mRNA into a linear sequence of amino acids in a protein.

codon Three nucleotides in messenger RNA that direct the placement of a particular amino acid into a polypeptide chain. (Contrast with anticodon.)

stop codon Any of the three mRNA codons that signal the end of protein translation at the ribosome: UAG, UGA, UAA. (Contrast with start codon.)

▶ 14.4 Eukaryotic Pre-mRNA Transcripts Are Processed prior to Translation

- Unlike prokaryotes, where transcription and translation occur in the cytoplasm and are coupled, in eukaryotes transcription occurs in the nucleus and translation later in the cytoplasm. [Review Table 14.2](#)
- Eukaryotic genes contain [introns](#), which are noncoding sequences within the transcribed regions of genes. [Review Figures 14.6B, 14.7](#)

intron Portion of a gene within the coding region that is transcribed into pre-mRNA but is spliced out prior to translation. (Contrast with exon.)

- The initial transcript of a eukaryotic protein-coding gene is modified with a **5' cap** and a **3' poly A tail**. [Review Figure 14.8](#)

poly A tail A long sequence of adenine nucleotides (50–250) added after transcription to the 3' end of most eukaryotic mRNAs.

- Pre-mRNA introns are removed in the nucleus via [RNA splicing](#). Then the mRNA passes through the nuclear pore into the cytoplasm, where it is translated through [ribosomes](#). **Review** [Figure 14.9](#), [Animation 14.3](#)

RNA splicing The last stage of RNA processing in eukaryotes, in which the transcripts of introns are excised through the action of small nuclear ribonucleoprotein particles (snRNP).

ribosome A small particle in the cell that is the site of protein synthesis.

► 14.5 The Information in mRNA Is Translated into Proteins

See [Animation 14.4](#)

- During translation, amino acids are linked together in the order specified by the codons in the mRNA. This task is achieved by tRNAs, each of which binds to (is charged with) a specific amino acid and has an [anticodon](#) complementary to a specific mRNA codon.

Review [Figures 14.10](#), [14.11](#)

anticodon The three nucleotides in transfer RNA that pair with a complementary triplet (a codon) in messenger RNA.

- The ribosome is the molecular workbench where translation occurs. It has one large and one small subunit, each made of [ribosomal RNA](#) and proteins.

ribosomal RNA (rRNA) Several species of RNA that are incorporated into the ribosome. Involved in peptide bond formation.

- Three sites on the large ribosomal subunit interact with tRNA. The A site is where the charged tRNA anticodon binds to the mRNA codon; the P site is where the tRNA adds its amino acid to the growing polypeptide chain; and the E site is where the tRNA is released. **Review** [Figure 14.12](#)
- Translation occurs in three steps: initiation, elongation, and termination. The [initiation complex](#) consists of tRNA bearing the first amino acid, the small ribosomal subunit, and mRNA. **Review** [Figure 14.13](#)

initiation complex In protein translation, a combination of a small ribosomal subunit, an mRNA molecule, and the tRNA charged with the first amino acid coded for by the mRNA; formed at the onset of translation.

- The growing polypeptide chain is elongated by the formation of peptide bonds between amino acids, catalyzed by rRNA. **Review** [Figure 14.14](#)
- When a stop codon reaches the A site, it terminates translation by binding a release factor. **Review** [Figure 14.15](#)
- In a **polysome**, more than one ribosome moves along a strand of mRNA at one time. **Review** [Figure 14.16](#)

▶ 14.6 Polypeptides Can Be Modified and Transported during or after Translation

- [Signal sequences](#) of amino acids direct polypeptides to the cellular destinations, such as organelles. **Review** [Figures 14.17](#), [14.18](#)

signal sequence The sequence within a protein that directs the protein to a particular organelle.

- Proteins addressed to the RER bind to a receptor protein in the RER membrane. **Review** [Figure 14.17](#)
- Posttranslational modifications of polypeptides include [proteolysis](#), whereby a polypeptide is cut to smaller fragments; [glycosylation](#), whereby sugars are added; and [phosphorylation](#), whereby phosphate groups are added. **Review** [Figure 14.19](#)

proteolysis [protein + Gk. *lysis*: break apart] An enzymatic digestion of a protein or polypeptide.

glycosylation The addition of carbohydrates to another type of molecule, such as a protein.

phosphorylation Addition of a phosphate group.

Review

4.1 Experimental evidence supports the claim that each gene encodes one protein.

Original Paper: Gross, S. R. 1965. The regulation of synthesis of leucine biosynthetic enzymes in *Neurospora*. *Proceedings of the National Academy of Sciences USA* 54:1538–1546.

The fungus *Neurospora crassa* first drew researchers' attention as a common contaminant in French bakeries, and it quickly proved to be an exceptional model for research. Its nutritional requirements are simple, it grows quickly and easily in the lab, and it follows the rules of Mendelian genetics.

In one study, researchers experimented with *Neurospora* to identify the steps in the biosynthesis of the amino acid leucine. The figure below shows a partial pathway that was proposed early in this research.

Neurospora is haploid for most of its life cycle. During sexual reproduction, haploid cells of two different mating types fuse, producing a diploid cell that carries both sets of parental genes. *Neurospora* grows on minimal medium without added amino acids because it can synthesize all of the amino acids and other compounds it needs to carry out its metabolic functions.

With these properties in mind, the researchers isolated two mutant *Neurospora* strains and tested them for growth on various media. Fused cells produced from mating between the two *Neurospora* mutants were isolated and tested in the same way. The results are shown in the table, where “+” indicates growth and “–” indicates no growth.

Questions

1. Analyze the data to identify which mutation is associated with which step (A, B, C, D) in the biosynthetic pathway. Explain your reasoning.
2. Explain why the fusion of two mutant cells is able to restore the wild-type phenotype.
3. Predict the data that would be collected if the activities of the enzymes catalyzing steps A, B, C, and D were measured in each haploid mutant and in the fused diploid cells.
4. Suppose the enzyme catalyzing a single step in a metabolic pathway consists of four subunits, and that the quaternary structure for this enzyme has the structure $\alpha_2\beta_2$, where α and β each represent a different polypeptide chain. Experiments with haploid cells of two mutant strains of *Neurospora* show that they are deficient in this metabolic step. However, diploid cells resulting from fusion between these two strains results in restoration of the wild-type phenotype. Explain these observations.

Strain	Minimal medium	Minimal medium + leucine	Minimal medium + 2-isopro-pylmalate	Minimal medium + 3-isopro-pylmalate	Minimal medium + α -ketoiso-caproate
Wild type (haploid)	+	+	+	+	+
<i>Leu-1</i> (haploid)	–	+	–	–	+
<i>Leu-2</i> (haploid)	–	+	–	+	+
Fused cells (diploid): <i>Leu-1, Leu-2</i>	+	+	+	+	+

The Angelina Jolie Effect

The actress Angelina Jolie surprised many people by announcing that she had had both breasts removed upon learning that she carries a mutation in the “breast cancer gene.” Ms. Jolie had good reason to be concerned: even without genetic tests, her family history suggests a high risk for cancer. Her mother had breast cancer and died at age 56 of ovarian cancer. Her aunt died of breast cancer. Her grandmother died of ovarian cancer. Jolie learned that a mutation in a gene called **BRCA1** can be responsible for hereditary ovarian and breast cancers and that her DNA for this gene could be sequenced and analyzed for mutations before cancer symptoms arise. A woman with a harmful mutation in the **BRCA1** gene has an 80 percent chance of getting breast cancer by age 60, far in excess of the 8 percent likelihood for women without a mutation. Removal of breast tissue lowers this risk to 10 percent.

Ms. Jolie’s announcement was widely praised by health-care professionals. Women at risk for a **BRCA1** mutation increasingly have elected to be tested, and more of those identified to be at an increased risk for breast cancer have chosen preventive surgery. Jolie’s announcement has helped women who have made these decisions feel less emotionally isolated.

The **BRCA1** mutation test is the culmination of research in the molecular genetics of cancer. As we discussed in [Chapter 11](#), cancer can arise through mutations of either oncogenes (resulting in overstimulation of the cell cycle) or tumor suppressor genes (which would otherwise function to slow down the cell cycle). **BRCA1** is a tumor suppressor gene involved in DNA repair. When the protein encoded by the gene is faulty because of gene mutation, unrepaired mutations accumulate in breast cell DNA, and some of these mutations improperly activate the cell cycle, resulting in uncontrolled cell division and other adverse effects of a growing tumor. Because **BRCA1** is also expressed in ovary tissue, women who are mutation carriers often have their ovaries removed as well; Ms. Jolie had this surgery two years after her breasts were removed.

The precise description of mutations in genetically caused diseases exemplifies the emerging field of molecular medicine. Our ability to identify mutations is leading to more precise testing, diagnoses, and treatments for the diseases they cause.

QA What is the breast cancer gene, and what are the issues with DNA testing for cancer?

15.1 Mutations Are Heritable Changes in DNA

In [Chapter 12](#) we defined mutations as stable, inherited changes in genes, and we saw that different alleles may produce different phenotypes (short pea plants versus tall, for example). In the two chapters that followed we described the chemical nature of genes as DNA sequences, and how they are expressed as phenotypes (in particular, proteins). To reiterate, we can now define a [mutation](#) as a change in the nucleotide sequence of DNA that can be passed on from one cell, or organism, to another.

mutation A change in the genetic material not caused by recombination.

focus your learning

Mutations that occur at the nucleotide sequence level can be classified by the specific changes they cause in DNA and phenotypic effects in proteins.

Mutations that occur at the chromosomal level can be classified by the specific changes they cause in chromosomes.

Induced mutations are caused by mutagens, which are environmental factors such as chemicals and radiation that alter DNA structure.

Mutation hot spots occur where bases are more susceptible to mutation.

Mutations have different phenotypic effects

Mutations are classified generally by the type of cell in which they occur:

[Somatic mutations](#) occur in somatic (nongamete) cells. These mutations are passed on to the daughter cells during mitosis, and to the daughters of those cells in turn, but are not passed on to sexually produced offspring. For example, a mutation in a single human skin cell could result in a patch of skin cells that all have the same mutation, but it would not be passed on to the person's children.

[Germ line mutations](#) occur in the cells of the germ line—the specialized cells that give rise to gametes. A gamete with the mutation passes it on to a new organism at fertilization. The new organism will have the mutation in every cell of its body and will be able to pass the mutation on to its offspring. The *BRCA1* mutation that Angelina Jolie, her aunt, and her mother inherited from Angelina's grandmother is a germ line mutation.

somatic mutation Permanent genetic change in a somatic cell (as opposed to a germ cell, the egg or sperm). These mutations affect the individual only; they are not passed on to offspring. (Contrast with germ line mutation.)

germ line mutation Mutation in a cell that produces gametes (i.e., a germ line cell). (Contrast with somatic mutation.)

Does every mutation have a phenotypic effect? Not necessarily. Some mutations have effects on proteins and their function, and some do not (**Focus: Key Figure 15.1**):

focus: key figure

(A) Normal allele: Codes for a functional protein

(B) Silent mutation: Does not affect protein function

(C) Loss-of-function mutation: Codes for a nonfunctional protein

(D) Gain-of-function mutation: Codes for a protein with a new function

Figure 15.1 Mutation and Phenotype Mutations may or may not affect the protein phenotype.

Q: For a protein coding gene, which of the three types of mutation will be most common, and why?

▶ Activity 15.1 **Mutations and Function Simulation** www.Life11e.com/ac15.1

▶ Activity 15.2 **Point Mutations Simulation** www.Life11e.com/ac15.2

A **silent mutation** does not usually affect protein function (see [Figure 15.1B](#)). It can be a mutation in a region of DNA that does not encode a protein, or it can be in the coding region of a gene but not affect the amino acid sequence. Because of the redundancy of the genetic code, a base change in a coding region will not always cause a change in the amino acid sequence when the altered mRNA is translated (see [Figure 15.2](#)). Silent mutations are common, and they usually result in genetic diversity that is not expressed as phenotypic differences.

A **loss-of-function mutation** affects protein function (see [Figure 15.1C](#)). Such a mutation may cause a gene to not be expressed at all, or the gene may be expressed but produces a dysfunctional protein that can no longer play its cellular role, such as its catalytic function if it is an enzyme. Loss-of-function mutations almost always show recessive inheritance in diploid organisms, because the presence of one wild-type allele will usually result in sufficient functional protein for the cell. For example, recall from [Key Concept 12.1](#) that the familiar wrinkled seed allele in pea plants, originally studied by Mendel, is due to a recessive loss-of-function mutation in the *SBE1* (starch branching enzyme) gene. Normally the protein made by this gene catalyzes the branching of starch as seeds develop. In the mutant, the SBE1 protein is not functional, and that leads to osmotic changes, causing the wrinkled appearance.

A **gain-of-function mutation** leads to a protein with an altered function (see [Figure 15.1D](#)). A gain-of-function mutation usually shows dominant inheritance, because the presence of the wild-type allele does not prevent the mutant allele from functioning. This type of mutation is common in cancer. For example, there are mutations in oncogenes that result in proteins that constantly stimulate cell division.

silent mutation A change in a gene's sequence that has no effect on the amino acid sequence of a protein either because it occurs in noncoding DNA or because it does not change the amino acid specified by the corresponding codon. (Contrast with frame-shift mutation, missense mutation, nonsense mutation.)

loss-of-function mutation A mutation that results in the loss of a functional protein. (Contrast with gain-of-function mutation.)

gain-of-function mutation A mutation that results in a protein with a new function. (Contrast with loss-of-function mutation.)

Figure 15.2 Point Mutations When they occur in the coding regions of proteins, single base changes can cause silent, missense, nonsense, or frame-shift mutations.

Some mutations have effects on phenotype only under certain conditions. For example, a **conditional mutation** affects phenotype only under restrictive conditions and is not detectable under what are called permissive conditions. Many conditional mutations are temperature-sensitive, resulting in proteins with reduced stability at high temperatures. For example, the point restriction phenotype in rabbits and Siamese cats (see [Figure 12.13](#)) is due to a temperature-

sensitive (conditional, loss-of-function) mutation in a coat color gene. At body temperature, the protein encoded by the gene is unstable and nonfunctional, so that the animal has dark fur only in its cooler extremities.

conditional mutation A mutation that results in a characteristic phenotype only under certain environmental conditions.

Most point mutations can be reversed; **reversion mutations** result when a gene is mutated a second time so that the DNA reverts to its original sequence or to a coding sequence that results in the non-mutant phenotype. When reversion mutations occur, the phenotype reverts to wild type.

reversion mutation A second- or third-round mutation that reverts the DNA to its original sequence or to a new sequence that results in a non-mutant phenotype.

Now let's look more closely at the DNA level to see how various kinds of mutations play out.

Point mutations are changes in single nucleotides

A **point mutation** is the addition or subtraction of a single nucleotide, or the substitution of one nucleotide base for another. There are two kinds of base substitution:

point mutation A mutation that results from the gain, loss, or substitution of a single nucleotide. (Contrast with deletion, duplication.)

- . A **transition** is the substitution of one purine for the other purine, or one pyrimidine for the other:
- . A **transversion** is the substitution of a purine for a pyrimidine, or vice versa:

transition In genetics, a mutation such that a purine base is converted to the other purine (e.g., adenine to guanine) or a pyrimidine to the other pyrimidine (e.g., C to T)

transversion A mutation that changes a purine to a pyrimidine or vice versa.

A point mutation in the coding region of a gene will result in an alteration in the mRNA sequence. But remember: a change in the mRNA does not necessarily mean a change in the protein that gets translated from it at the ribosome. As we just mentioned, a silent mutation has no effect on the amino acid sequence of an encoded polypeptide. By contrast, missense, nonsense, and frame-shift mutations do result in changes in the protein, some of them drastic ([Figure 15.2](#)).

MISSENSE MUTATIONS

Missense mutations are ***base substitution** changes that alter the genetic code such that one amino acid substitutes for another in a protein (see [Figure 15.2C](#)). A specific example is the mutation that causes sickle-cell disease, a serious heritable blood disorder. The disease occurs in people who carry two copies of the sickle allele of the gene for β -globin—a subunit of hemoglobin, the protein in human blood that carries oxygen. The sickle allele differs from the wild-type allele by one base pair, resulting in a polypeptide that differs by one amino acid from the wild-type protein. Individuals who are homozygous for this recessive allele have defective, sickle-shaped red blood cells:

missense mutation A change in a gene's sequence that changes the amino acid at that site in the encoded protein. (Contrast with frame-shift mutation, nonsense mutation, silent mutation.)

Media Clip 15.1 **Sickle Cells: Deformed by a Mutation** www.Life11e.com/mc15.1

A missense mutation may result in a defective protein, but often has no effect on the protein's

function. For example, a hydrophilic amino acid may be substituted for another hydrophilic amino acid, so that the shape of the protein is unchanged. Or a missense mutation might reduce the functional efficiency of a protein rather than completely inactivating it. Therefore individuals homozygous for a missense mutation in a protein essential for life may survive if enough of the protein's function is retained.

In some cases, a gain-of-function missense mutation occurs. An example is a mutation in the human *P53* gene, which codes for a tumor suppressor—a protein that inhibits the cell cycle (see [Key Concept 11.7](#)). Certain mutations of the *P53* gene cause this protein to no longer inhibit cell division, but instead to promote it and prevent programmed cell death.

NONSENSE MUTATIONS

A **nonsense mutation** involves a base substitution that causes a stop codon (for translation) to form somewhere in the mRNA (see [Figure 15.2D](#)). A nonsense mutation results in a shortened protein, since translation does not proceed beyond the point where the mutation occurred. For example, a common mutation causing thalassemia (another blood disorder affecting hemoglobin) in Mediterranean populations is a nonsense mutation that drastically shortens the β -globin subunit. Shortened proteins are usually not functional; however, if the nonsense mutation occurs near the 3' end of the gene, it may have no effect on function.

nonsense mutation Change in a gene's sequence that prematurely terminates translation by changing one of its codons to a stop codon. (Contrast with frame-shift mutation, missense mutation, silent mutation.)

FRAME-SHIFT MUTATIONS

Not all point mutations are base substitutions. One or two nucleotides may be inserted into, or deleted from, a sequence of DNA. Such mutations in coding sequences are known as **frame-shift mutations** because they alter the reading frame (that is, consecutive triplets) in which the codons are read during translation (see [Figure 15.2E](#)). Think again of ***codons** as three-letter words, each corresponding to a particular amino acid. Translation proceeds codon by codon; if a nucleotide is added to the mRNA or subtracted from it, then the three-letter “words” are altered as translation proceeds beyond that point, and the result is a completely different amino acid sequence. Frame-shift mutations almost always lead to the production of nonfunctional proteins.

frame-shift mutation The addition or deletion of a single or two adjacent nucleotides in a gene's sequence. Results in the misreading of mRNA during translation and the production of a nonfunctional protein. (Contrast with missense mutation, nonsense mutation, silent mutation.)

MUTATIONS OUTSIDE THE CODING REGION

As discussed in [Chapter 17](#), in genomes like ours, much of the DNA does not contain protein-coding genes. If there is a mutation in a region that is not involved with a protein-coding gene, it often does not have a phenotypic effect, although it is still a mutation—an inherited change in DNA. Recall from [Chapter 14](#) that protein-coding genes have stretches of DNA that do not encode amino acids, such as promoters and introns. Mutations in these regions may have significant effects. For example:

promoter mutations may alter the rate of transcription of the gene.

mutations at RNA splicing sites may lead to abnormal mRNA.

Chromosomal mutations are extensive changes in the genetic material

Changes in single nucleotides are not the most dramatic changes that can occur in the genetic material. Whole DNA molecules (that is, whole chromosomes) can break and rejoin, grossly disrupting the sequence of genetic information. There are four types of such **chromosomal mutations**: deletions, duplications, inversions, and translocations. These mutations can be caused by severe damage to chromosomes resulting from mutagens or by drastic errors in chromosome replication.

chromosomal mutation Loss of or changes in position/direction of a DNA segment on a chromosome.

A **deletion** occurs by the removal of part of the genetic material and can happen if a chromosome breaks at two points and then rejoin, leaving out the DNA between the breaks (**Figure 15.3A**).

A **duplication** can be produced at the same time as a deletion and can occur if homologous chromosomes break at different positions and then reconnect to the wrong partners (**Figure 15.3B**). One of the two chromosomes ends up with a deleted segment, and the other has two copies (a duplication) of the same segment.

An **inversion** can also result from the breaking and rejoining of a chromosome, and can occur if a segment of DNA becomes “flipped,” so that it runs in the opposite direction from its original orientation (**Figure 15.3C**).

A **translocation** results when a segment of a chromosome breaks off and becomes attached to a different chromosome. As we mentioned in **Key Concept 11.5**, a translocation of a large segment of chromosome 21 is one cause of Down syndrome. Translocations may involve reciprocal exchanges of chromosome segments, as in **Figure 15.3D**.

deletion A mutation resulting from the loss of a continuous segment of a gene or chromosome. Such mutations almost never revert to wild type. (Contrast with duplication, point mutation.)

duplication A mutation in which a segment of a chromosome is duplicated, often by the attachment of a segment lost from its homolog. (Contrast with deletion.)

inversion A rare 180° reversal of the order of genes within a segment of a chromosome.

translocation (1) In genetics, a rare mutational event that moves a portion of a chromosome to a new location, generally on a nonhomologous chromosome. (2) In vascular plants, movement of solutes in the phloem.

(A) Deletion

Figure 15.3 Chromosomal Mutations Chromosomes may break during replication, and parts of chromosomes may then rejoin incorrectly. This can result in deletions (A, B), duplications (B), inversions (C), or reciprocal translocations (D). Note that the letters on these illustrations represent large segments of the chromosomes. Because chromosomes contain regions of noncoding DNA, each segment may include anywhere from zero to hundreds or thousands of genes.

Q: How are chromosomal mutations detected? Hint: See [Figure 11.20](#).

Retroviruses and transposons can cause loss-of-function mutations or duplications

[Key Concept 14.2](#) described how certain viruses called retroviruses can insert their genetic material into the host cell's genome. Such insertions happen at random, and if one occurs within a gene, it can cause a loss-of-function mutation in that gene. In many cases, the viral DNA remains in the host genome and is passed on from one generation to the next. When this happens the virus is called an endogenous retrovirus. Endogenous retroviruses are common—in fact, they make up 5 to 8 percent of the human genome.

Another form of DNA, called a transposon or transposable element, can also insert itself into genes and cause mutations. As you will see in [Chapter 17](#), transposons are widespread in both prokaryotic and eukaryotic genomes. A transposon is a DNA sequence of a few hundred to a few thousand base pairs that can move from one position in the genome to another. It usually carries genes that encode the enzymes needed for this movement. Some transposons remove themselves from their positions in the genome and then insert themselves into other sites (the “cut and paste” mode of transposition). These transposons do not always excise cleanly, but leave behind short sequences of a few base pairs that become permanent mutations in the affected genes. Other transposons first replicate themselves, and then the new copies are inserted into new sites in the genome (the “copy and paste” mode). A sequence of genomic DNA is sometimes carried along with the transposon DNA when it moves, and gene duplication occurs. As you'll see, gene duplication plays an important role in evolution.

Mutations can be spontaneous or induced

It is useful to distinguish between mutations that are spontaneous or induced, based on their causes. [Spontaneous mutations](#) are permanent changes in the genetic material that occur

without any outside influence. The movement of transposons is an example of spontaneous mutation. Spontaneous mutations can also occur because cellular processes are imperfect, and may occur by several mechanisms:

spontaneous mutation A genetic change caused by internal cellular mechanisms, such as an error in DNA replication. (Contrast with induced mutation.)

A transient rearrangement in the structure of a nucleotide base can result in mistakes during replication. Each base can exist in two different forms (called tautomers), one of which is common and one rare. When a base temporarily forms its rare tautomer, it can pair with the wrong base. For example, C normally pairs with G, but if C takes on the form of its rare tautomer at the time of DNA replication, it pairs with (and DNA polymerase will insert) an A. If this is passed on to a daughter cell after cell division, the result is a point mutation: G → A (Figure 15.4A and C).

Figure 15.4 Spontaneous and Induced Mutations (A) All four nitrogenous bases in DNA exist in both a prevalent (common) form and a rare form. When a base spontaneously forms its rare tautomer, it can pair with a different base. (B) Mutagens such as nitrous acid (HNO_2) can induce changes in the bases. (C) The results of both spontaneous and induced mutations are permanent changes in the DNA sequence following replication.

A chemical reaction may alter the structure of a DNA base. For example, a deamination reaction can result in loss of the amino group (NH_2) attached to carbon 4 in cytosine. If this

occurs in a DNA molecule, the error will usually be repaired. However, since the repair mechanism is not perfect, the altered nucleotide will sometimes remain during replication. In these cases, DNA polymerase will add an A (which base-pairs with U on the template DNA) instead of G (which normally pairs with C).

DNA polymerase can make errors in replication (see [Key Concept 13.4](#))—for example, by inserting a T opposite a G. Most of these errors are repaired by the proofreading function of the replication complex, but some errors escape detection and become permanent.

Meiosis is not perfect. Nondisjunction—the failure of homologous chromosomes to separate during meiosis—can occur, leading to one too many chromosomes or one too few (see [Figure 11.19](#)). Random chromosome breakage and rejoining can produce deletions, duplications, inversions, or translocations.

Induced mutations occur when some agent from outside the cell— a **mutagen**—causes a permanent change in DNA. As we mentioned above, retroviruses can function as mutagens. In addition, certain chemicals and radiation can cause mutations:

induced mutation A mutation resulting from exposure to a mutagen from outside the cell. (Contrast with spontaneous mutation.)

mutagen (mute' ah jen) [L. *mutare*: change + Gk. *genesis*: source] Any agent (e.g., a chemical, radiation) that increases the mutation rate.

Some chemicals can alter nucleotide bases. For example, nitrous acid (HNO₂) and similar molecules can react with cytosine and convert it to uracil by deamination. More specifically, they convert an amino group on the cytosine (—NH₂) into a keto group (—C=O) ([Figure 15.4B](#)). This alteration has the same result as spontaneous deamination: instead of a G, DNA polymerase inserts an A (see [Figure 15.4C](#)).

Some chemicals add groups to the bases. For instance, benzopyrene, a component of cigarette smoke, adds a large chemical group to guanine, making it unavailable for base pairing. When DNA polymerase reaches such a modified guanine, it inserts any one of the four bases at random. Three-fourths of the time the inserted base is not cytosine, and a mutation results.

Radiation damages the genetic material. Radiation can damage DNA in two ways. First, ionizing radiation (including X rays, gamma rays, and radiation from unstable isotopes) produces highly reactive chemicals called free radicals. Free radicals can change bases in DNA to forms that are not recognized by DNA polymerase. Ionizing radiation can also break the sugar–phosphate backbone of DNA, causing chromosomal abnormalities. Second, ultraviolet radiation (from the sun or a tanning lamp) is absorbed by thymine, causing it to form covalent bonds with adjacent bases. This, too, plays havoc with DNA replication by distorting the double helix.

Mutagens can be natural or artificial

Many people associate mutagens with materials made by humans, but many mutagenic substances are found in nature. An example of a naturally occurring mutagen is aflatoxin, which is made by the mold *Aspergillus*. When mammals ingest the mold, the aflatoxin is converted by the smooth endoplasmic reticulum in liver cells into a product that, like benzopyrene from cigarette smoke, binds to guanine; this also causes mutations. Plants (and to a lesser extent animals) make thousands of small molecules with a variety of functions, some of which are mutagenic and potentially carcinogenic. Examples of human-made mutagens are nitrites, which

are used to preserve meats. Once in mammals, nitrites get converted by the smooth endoplasmic reticulum (SER) to nitrosamines, which are strongly mutagenic because they cause deamination of cytosine (see [Figure 15.4](#)).

Radiation can also be human-made or natural. Some of the isotopes made in nuclear reactors and nuclear bomb explosions are certainly harmful. For example, extensive studies have shown increased mutations in the survivors of the atom bombs dropped on Japan in 1945. As previously mentioned, natural ultraviolet radiation in sunlight also causes mutations.

By now, you may be getting worried about all the ways your DNA can be mutated. But for us, and most organisms, DNA repair mechanisms have evolved so that most changes in DNA do not get passed on to either the daughter cells or the next generation (see [Figure 13.18](#)). Biochemists have estimated how much DNA damage occurs in the human genome under normal circumstances: among the genome's 3.2 billion base pairs, there are about 16,000 DNA-damaging events per cell per day, of which 80 percent are repaired.

Some base pairs are more vulnerable than others to mutation

In certain regions of DNA, many of the cytosine residues have methyl groups added at their 5 positions, forming 5-methylcytosine. Methylation plays an important role in gene regulation (discussed in [Key Concept 16.4](#)). DNA sequencing has revealed that mutation “hot spots” are often located where cytosines have been methylated. [Figure 15.4](#) shows unmethylated cytosine, which can lose its amino group, either spontaneously (see [Figure 15.4A](#)) or because of a chemical mutagen, to form uracil (see [Figure 15.4B](#)). This type of error is usually detected by the cell and repaired, because uracil is recognized as inappropriate for DNA. However, when 5-methylcytosine (methylated cytosine) loses its amino group, the product is thymine, a natural base for DNA ([Figure 15.5](#)). The DNA repair mechanism ignores this thymine. During replication, however, the mismatch repair mechanism recognizes that G-T is a mismatched pair, although it cannot tell which base is incorrect. Half of the time it matches a new C to the G, but the other half of the time it matches a new A to the T, resulting in a mutation.

Figure 15.5 5-Methylcytosine in DNA Is a “Hot Spot” for Mutations If cytosine has been methylated to 5-methylcytosine, the mutation is unlikely to be repaired and a C-G base pair is replaced with a T-A pair.

Mutations have both benefits and costs

As we will see in [Part Seven](#) of this book, mutations are the raw material of evolution: they provide the genetic diversity that makes natural selection possible. This diversity can be beneficial in two ways. First, a mutation in a somatic cell may benefit the organism immediately. Second, a mutation in a germ line cell may have no immediate selective advantage to the organism, but it may cause a phenotypic change in the organism's offspring. If the environment

changes in a later generation, this mutation may be advantageous, and thus selected for, under the new conditions.

We noted that gene duplication can arise through either chromosomal rearrangements or through the movements of transposons. Gene duplication is not always harmful and is an important source of genetic variation. In a duplicated pair of genes, one gene may continue to play its original role in the cell, while the other may acquire a gain-of-function mutation that produces a new phenotype. As with any other mutation, this may be of immediate benefit for the organism, or it may provide a later generation with a selective advantage.

By contrast, mutations in genes whose products are needed for normal cellular processes are often harmful, especially if they occur in germ line cells that produce eggs or sperm. In such cases, some offspring can inherit harmful recessive alleles in the homozygous condition. In their extreme form, such mutations produce phenotypes that are lethal, killing the organism during early development. Likewise, mutations in somatic cells can be harmful, as in the case of cancer. Think about what would happen if an oncogene that stimulates cell division in a colon cell had a gain-of-function mutation in an adult. The result would be the same as inheriting the mutant allele: colon cancer.

What can we do about mutation? While spontaneous mutagenesis is not in our control, we can certainly try to avoid mutagenic substances and radiation. Not surprisingly, many things that cause cancer (carcinogens) are also mutagens. A good example is benzopyrene (discussed above), which is found in coal tar, car exhaust fumes, and charbroiled foods, as well as in cigarette smoke. A major public-policy goal is to reduce the effects of both human-made and natural mutagens on human health. An example is the Montreal Protocol, an international environmental agreement signed and adhered to by all members of the United Nations. It bans chlorofluorocarbons and other substances that cause depletion of the ozone layer in the upper atmosphere of Earth. The thinning of the ozone layer can result in increased ultraviolet radiation reaching Earth's surface, which is implicated in somatic mutations that lead to skin cancer.

15.1 recap

Mutations are uncorrected alterations in the nucleotide sequence of DNA. Mutations can involve changes in single nucleotides or extensive rearrangements of chromosomes. If they occur in somatic cells, they will be passed on to daughter cells; if they occur in germ line cells, they may be passed on to offspring.

learning outcomes

You should be able to:

- Use a defined DNA sequence to illustrate how the following occur, and describe their effect on phenotype: transitions, transversions, missense mutations, nonsense mutations, frame-shift mutations, and mutations outside the coding region of a gene.
- Compare the following chromosomal mutations: deletion, duplication, inversion, and translocation.
- Compare and contrast spontaneous and induced mutations and give examples of each.
- Explain why some regions of DNA are considered mutation hot spots.

1. What are the differences between point mutations that cause phenotypic changes and those that don't?
2. What distinguishes the various kinds of chromosomal mutations: deletions, duplications,

inversions, and translocations?

- [3.](#) What are the differences between spontaneous and induced mutagenesis? Give an example of each.
- [4.](#) Why do many mutations involve G-C base pairs?

You have seen that there are many different ways in which DNA can be altered, in terms of both the types of changes and the mechanisms by which they occur. We will turn now to the ways in which mutations can cause disease.

*** connect the concepts** Many base substitution mutations result in changes in protein structure due to amino acid substitutions. Review the relationships between amino acid sequence and protein three-dimensional structure in [Key Concept 3.2](#).

***connect the concepts** Even in a protein-encoding region, some mutations do not affect amino acid sequence because of redundancies in the genetic code. The genetic code provides more than one codon for most of the amino acids. See [Key Concept 14.3](#).

15.2 Mutations in Humans Can Lead to Diseases

The biochemistry that relates genotype (DNA) and phenotype (proteins) has been most completely described for model organisms, such as the prokaryote *E. coli* and the eukaryotes yeast and *Drosophila*. While the details vary, there is great similarity in the fundamental processes among these forms of life. These similarities have permitted the application of knowledge and methods discovered using these model organisms to the study of human biochemical genetics. Our focus in this chapter is mutations that affect human phenotypes, leading to diseases.

focus your learning

Genetic diseases often result from mutations that render proteins nonfunctional.

Mutations that cause disease include the full range of affected DNA from point mutations to entire chromosomes.

Most diseases result from a combination of factors that include both genetics and the environment.

Disease-causing mutations may make proteins dysfunctional

Genetic mutations are often expressed phenotypically as proteins that differ from normal (wild-type) proteins. Abnormalities in enzymes, receptor proteins, transport proteins, structural proteins, and most of the other functional classes of proteins have all been implicated in genetic diseases.

LOSS OF ENZYME FUNCTION

In 1934, the urine of two intellectually disabled young siblings was found to contain phenylpyruvic acid, an unusual by-product of the metabolism of the amino acid phenylalanine. It took two decades for scientists to trace the complex clinical phenotype of the disease that afflicted these children, called phenylketonuria (PKU), back to its molecular cause. The disease results from an abnormality in a single enzyme, phenylalanine hydroxylase (PAH), which catalyzes the conversion of dietary phenylalanine to tyrosine ([Figure 15.6](#)). This enzyme is not active in the livers of PKU patients, leading to excesses of phenylalanine and phenylpyruvic acid in the blood. Since then, the nucleotide sequence of the *PAH* gene has been compared between healthy people and those with the PKU disease, and more than 400 different disease-causing mutations have been found. The most common one is a missense mutation that results in tryptophan instead of arginine at position 408 in the polypeptide chain ([Table 15.1](#)). As is often the case with loss-of-function mutations, the mutant alleles are recessive, because one functional allele is all that is needed to produce enough functional PAH to prevent the disease.

Figure 15.6 One Gene, One Enzyme Phenylketonuria is caused by an abnormality in a specific enzyme that metabolizes the amino acid phenylalanine. Knowing the molecular causes of such single-gene, single-enzyme metabolic diseases can aid researchers in developing screening tests as well as treatments.

table 15.1 Two Common Mutations That Cause Phenylketonuria

	Codon 408 (20% of PKU cases)		Codon 280 (2% of PKU cases)	
	Normal	Mutant	Normal	Mutant
Length of PAH protein	452 amino acids	452 amino acids	452 amino acids	452 amino acids
DNA at codon	...CGG...	...TGG...	...GAA...	...AAA...
	...GCC...	...ACC...	...CIT...	...TTT...
mRNA at codon	...CGG...	...UGG...	...GAA...	...AAA...
Amino acid at codon	Arginine	Tryptophan	Glutamic acid	Lysine
Active PAH enzyme?	Yes	No	Yes	No

Hundreds of human genetic diseases that result from enzyme abnormalities have been discovered, some of which lead to intellectual disability and premature death. Most of these diseases are rare; PKU, for example, shows up in 1 out of every 12,000 newborns. As you by now realize, for any given gene there may be numerous alleles. Some alleles encode proteins that function normally, whereas others produce proteins that cause disease. Let's take a look at a gene whose alleles illustrate both of these circumstances—the gene for one of the polypeptide chains in hemoglobin.

ABNORMAL HEMOGLOBIN

As mentioned in [Key Concept 15.1](#), sickle-cell disease is caused by a recessive, missense mutation. This blood disorder most often afflicts people whose ancestors came from the tropics or from the Mediterranean region.

Recall that human hemoglobin is composed of four globin sub-units—two α -chains and two β -chains—as well as the pigment heme (see [Figure 3.11](#)). In sickle-cell disease, one of the 146 amino acids in the β -globin polypeptide chain is abnormal: at position 6, glutamic acid is replaced by valine. This replacement changes the charge of the protein (glutamic acid is hydrophilic and valine is hydrophobic), causing it to form long, needlelike aggregates in the red

blood cells. The phenotypic result is sickle-shaped red blood cells and an impaired ability of the blood to carry oxygen. The sickled cells tend to block narrow blood capillaries, resulting in tissue damage and eventually death by organ failure.

Because hemoglobin is easy to isolate and study, its variations in the human population have been extensively documented (Figure 15.7). Hundreds of single amino acid alterations in β -globin, all due to mutations forming alleles, have been reported. For example, at the same position that is mutated in sickle-cell disease (resulting in hemoglobin S), glutamic acid may be replaced by lysine, causing hemoglobin C disease. In this case, the resulting anemia is usually not severe. Many alleles that result in alterations of the amino acid sequence of hemoglobin do not affect its function. In fact, about 5 percent of us carry at least one missense point mutation in a β -globin allele.

		Amino acid position (of 146)								
		2	6	7	16	24	26	56	63	95
Variants of β -globin	A (wild type)	His	Glu	Glu	Gly	Gly	Glu	Gly	His	Lys
	Tokuchi	Tyr								
	S		Val							
	C		Lys							
	G			Gly						
	J Baltimore				Asp					
	Savannah					Val				
	E						Lys			
	Bangkok							Asp		
	Zürich								Arg	
	M Saskatoon								Tyr	
	N Baltimore									Glu

Only three hemoglobin variants (S, C, and E) lead to clinical problems.

Only three hemoglobin variants (S, C, and E) lead to clinical problems.

Figure 15.7 Hemoglobin Polymorphism Each of these mutant alleles codes for a protein with a single amino acid change in the 146-amino acid chain of β -globin. Only three of the hundreds of known variants of β -globin, shown on the left, are known to lead to clinical abnormalities. “S” is the sickle-cell anemia allele.

Some of the more common examples of inherited diseases caused by specific protein defects are listed in Table 15.2. These mutations can be dominant, codominant, or recessive, and some are sex-linked.

table 15.2 Some Human Genetic Diseases			
Disease name	Inheritance pattern; births frequency	Gene mutated; protein product	Clinical phenotype
Familial hypercholesterolemia	Autosomal codominant; 1 in 500 heterozygous	LDLR; low-density lipoprotein receptor	High blood cholesterol, heart disease
Cystic fibrosis	Autosomal recessive; 1 in 4,000	CFTR; chloride ion channel in membrane	Immune, digestive, and respiratory illness
Duchenne muscular dystrophy	Sex-linked recessive; 1 in 3,500 males	DMD; the muscle membrane protein dystrophin	Muscle weakness

Hemophilia A	Sex-linked recessive; 1 in 5,000 males	HEMA; factor VIII blood clotting protein	Inability to clot blood after injury, hemorrhage
--------------	--	--	--

Disease-causing mutations may involve any number of base pairs

Disease-causing mutations may involve a single base pair, a long stretch of DNA, multiple segments of DNA, or even entire chromosomes (as we saw for Down syndrome in [Key Concept 11.5](#)).

POINT MUTATIONS

Sickle-cell anemia is just one of many diseases caused by a point mutation. In some cases (sickle-cell anemia, for example), everyone with the disease has the same genetic mutation. In other cases, different loss-of-function point mutations in one gene can lead to the same disease (as we saw above for PKU). Think about it: the three-dimensional structure of an enzyme protein depends on its secondary structure, so any change in the amino acid sequence of a protein has the potential to affect its structure, and consequently its function.

LARGE DELETIONS

Larger mutations may involve many base pairs of DNA. For example, deletions in the X chromosome that include the gene for the protein dystrophin result in Duchenne muscular dystrophy. Dystrophin is important in organizing the structure of muscles, and people who have only the abnormal form have severe muscle weakness. Sometimes only part of the dystrophin gene is missing, leading to an incomplete but partly functional protein and a mild form of the disease. In other cases, deletions span the entire sequence of the gene, so that the protein is missing entirely, resulting in a severe form of the disease. In yet other cases, deletions involve millions of base pairs and cover not only the dystrophin gene but adjacent genes as well; the result may be several diseases in the same person.

CHROMOSOMAL ABNORMALITIES

Chromosomal abnormalities also cause human diseases. Such abnormalities result from the gain or loss of complete chromosomes (aneuploidy) (see [Figure 11.19](#)), or from the gain or loss of chromosomal segments (see [Figure 15.3](#)). About 1 newborn in 200 has a chromosomal abnormality. This may be inherited from a parent who also has the abnormality, or it may result from an error in meiosis during the formation of gametes in one of the parents. One example is fragile-X syndrome, which is a constriction in the tip of the X chromosome that can result in intellectual disability ([Figure 15.8](#)). About 1 male in 3,000 and 1 female in 7,000 are affected. Although the basic pattern of inheritance is that of an X-linked recessive trait, there are departures from this pattern. Not all people with the fragile-X chromosomal abnormality are intellectually disabled, as we will see.

Figure 15.8 A Fragile-X Chromosome at Metaphase The chromosomal abnormality

associated with fragile-X syndrome shows up under the microscope as a constriction in the chromosome. This occurs during preparation of the chromosome for microscopy.

Expanding triplet repeats demonstrate the fragility of some human genes

About one-fifth of all males who have the fragile-X chromosomal abnormality are phenotypically normal, as are most of their daughters. But many of those daughters' sons are intellectually disabled. In a family in which fragile-X syndrome appears, later generations tend to show earlier onset and more severe symptoms of the disease. It is almost as if the abnormal allele itself is changing—and getting worse. And that's exactly what is happening.

The gene associated with fragile-X syndrome (*FMR1*) contains a repeated triplet, CGG, at a certain point in the promoter region ([Figure 15.9](#)). In normal people, this triplet is repeated 6 to 54 times (the average is 29). In intellectually disabled people with fragile-X syndrome, the CGG sequence is repeated 200 to 2,000 times.

Figure 15.9 The CGG Repeats in the *FMR1* Gene Expand with Each Generation

The genetic defect in fragile-X syndrome is caused by 200 or more repeats of the CGG triplet.

Males carrying a moderate number of repeats (55–199) show no symptoms and are called premutated. These repeats become more numerous as the daughters of these men pass the chromosome on to their children. With 200 or more repeats, increased methylation of the cytosines in the CGG triplets is likely, which inhibits transcription of the *FMR1* gene. The normal role of the protein product of this gene is to bind to mRNAs involved in neuron function and to regulate their translation at the ribosome. When the *FMR1* protein is not made in adequate

amounts, these mRNAs are not properly translated, and nerve cells die. Their loss often results in intellectual disability. The methylated cytosines bind proteins that cause the chromosome constriction and fragile appearance.

This phenomenon of [expanding triplet repeats](#) has been found in more than a dozen other diseases, such as myotonic dystrophy (involving repeated CTG triplets) and Huntington's disease (in which CAG is repeated). Such repeats, which may be found within a protein-coding region or outside it, appear to be present in many other genes without causing harm. How the repeats expand is not known; one hypothesis is that DNA polymerase may slip after copying a repeat and then fall back to copy it again.

expanding triplet repeat A three-base-pair sequence in a human gene that is unstable and can be repeated a few to hundreds of times. Often, the more the repeats, the less the activity of the gene involved. Expanding triplet repeats occur in some human diseases such as Huntington's disease and fragile-X syndrome.

Cancer often involves somatic mutations

Many chromosomal and point mutations have been described in cancer cells. Such mutations affect [*oncogenes](#), whose products stimulate cell division, or tumor suppressor genes, whose products inhibit cell division. More than two gene mutations are usually needed for full-blown cancer.

Because colon cancer progresses to full malignancy slowly, it has been possible to identify the gene mutations that lead to each stage. [Figure 15.10](#) outlines the “molecular biography” of this form of cancer. At least three tumor suppressor genes and one oncogene must be mutated in sequence in a cell in the colon lining for cancer to develop. Although the occurrence of all of these events in a single cell might seem unlikely, remember that the colon lining has millions of cells, that these cells arise from stem cells that are constantly dividing, and that these changes take place over many years of exposure to natural and synthetic substances in foods, which may act as mutagens.

(A) Colon cancer development

(B) Normal versus cancerous colon

Figure 15.10 Multiple Somatic Mutations Transform a Normal Colon Epithelial Cell into a Cancer Cell (A) At least five genes must be mutated in a single cell to produce metastatic colon cancer. **(B)** These images from a screening test reveal a normal colon (left) and colon cancer (right).

Most diseases are caused by multiple genes and environment

The example of cancer illustrates how many common phenotypes, including ones that cause disease, are **multifactorial**; that is, they are caused by the interactions of many genes and proteins with one or more factors in the environment. When studying genetics, we tend to call individuals either normal (wild type) or abnormal (mutant); however, in reality every individual contains thousands or millions of genetic variations that arose through mutations. Our susceptibility to disease is often determined by complex interactions between these genotypes and factors in the environment, such as the foods we eat or the pathogens we encounter. For example, a complex set of genotypes determines who among us can eat a high-fat diet and not experience a heart attack, or who will succumb to disease when exposed to infectious bacteria. Estimates suggest that up to 60 percent of all people are affected by diseases that are genetically influenced. Identifying these genetic influences is another major task of molecular medicine and human genome sequencing.

multifactorial The interaction of many genes and proteins with one or more factors in the environment. For example, cancer is a disease with multifactorial causes.

15.2 recap

Many genetic mutations are expressed as nonfunctional enzymes, structural proteins, or membrane proteins. Human genetic diseases may be inherited in dominant, codominant, or recessive patterns, and they may be sex-linked.

learning outcomes

You should be able to:

- Describe an abnormal protein in humans that results from a genetic mutation and causes a disease.
- Show how the following mutations can lead to phenotypic change: point mutations, large deletions, and chromosomal abnormality.
- Justify the claim that most diseases arise from complex interactions between genetic and environmental factors.

1. Alkaptonuria is an inborn error of metabolism, caused by defects in an enzyme in the pathway that breaks down tyrosine (see [Key Concept 14.1](#)). Humans who are homozygous for one of these mutations make nonfunctional enzyme and accumulate the enzyme's substrate, homogentisic acid, which causes their disease symptoms. In 1996, researchers in Spain cloned and sequenced the gene for the enzyme, and characterized several mutant alleles. Here is the wild-type coding strand sequence for part of the gene, with the amino acid sequence of the protein below:

... TTG ATA CCC ATT GCC ...

... Leu Ile Pro Ile Ala ...

Here is the sequence for one of the mutant alleles:

... TTG ATA TCC ATT GCC ...

- a. What is the amino acid sequence produced by the mutant allele? What type of mutation is this: silent, nonsense, missense, or frame-shift?
 - b. Why is this mutation likely to affect the function of the enzyme? (Hint: see [Key Concept 3.2](#), especially [Table 3.2](#).)
2. Not all women with a mutation in the BRCA1 gene get early-onset breast cancer. Explain.
3. Why do some members of a family show symptoms of fragile-X syndrome and others do not?

In the previous section we described the ways in which mutations can lead to human disease. We will turn now to the ways that biologists detect mutations in DNA.

*** connect the concepts** You can learn more about the roles of oncogene and tumor suppressor gene mutations in the abnormal cell cycle of cancer cells in [Key Concept 11.7](#).

15.3 Mutations Can Be Detected and Analyzed

A challenge for biologists studying mutations is to precisely describe the DNA changes that lead to specific protein changes—an area of research called molecular genetics. Of course, the most direct and comprehensive way to analyze DNA is to determine its sequence of bases. DNA sequencing technologies are continually improving, and the entire genomes of many organisms have now been sequenced completely. Furthermore, the genomes of closely related organisms have been compared in order to identify mutations. We will discuss sequencing technology in [Chapter 17](#). We are approaching the era where DNA sequencing will be the method of choice in searching for mutations. DNA sequencing is not yet, however, in routine use in medicine. In this section we will look at some of the techniques that are used in combination with DNA sequencing to study DNA, and to identify mutations that cause disease.

focus your learning

DNA sequencing techniques provide great promise for identifying mutations as part of medical diagnosis and treatment.

Mutations in DNA can be used to look for disease.

Cleavage of DNA by restriction enzymes can be used to rapidly detect mutations

All organisms, including bacteria, must have ways of dealing with their enemies. As we saw in [Key Concept 13.1](#), bacteria can be attacked by viruses called bacteriophages. These viruses inject their genetic material into the host cell and turn it into a virus-producing factory, eventually killing the cell. Some bacteria defend themselves against such invasions by producing [restriction enzymes](#) (also known as restriction endonucleases), which cut double-stranded DNA molecules—such as those injected by bacteriophages—into smaller, noninfectious fragments ([Figure 15.11](#)). These enzymes break the bonds of the DNA backbone between the 3' hydroxyl group of one nucleotide and the 5' phosphate group of the next nucleotide. This cutting process is called [restriction digestion](#).

restriction enzyme Any of a type of enzyme that cleaves double-stranded DNA at specific sites; extensively used in recombinant DNA technology. Also called a restriction endonuclease.

restriction digestion An enzymatic reaction in which a molecule of DNA is fully cleaved by a restriction enzyme.

Figure 15.11 Bacteria Fight Invading Viruses by Making Restriction Enzymes

There are many such restriction enzymes, each of which cleaves DNA at a specific sequence of bases called a **recognition sequence** or a **restriction site**. Most recognition sequences are four to six base pairs long. Because each sequence of bases has a unique structure (see [Key Concept 13.2](#)), it can be specifically recognized by a particular restriction enzyme. Cells protect themselves from being digested by their own enzymes by modifying their DNA, often with methyl groups, to prevent binding by the restriction enzymes.

recognition sequence See restriction site.

restriction site A specific DNA base sequence that is recognized and acted on by a restriction endonuclease.

Restriction enzymes can be isolated from the cells that make them and used as biochemical reagents in the laboratory to give information about the nucleotide sequences of DNA molecules from other organisms. If DNA from any organism is incubated in a test tube with a restriction enzyme (along with buffers and salts that help the enzyme function), that DNA will be cut wherever the restriction site occurs. A specific sequence of bases defines each restriction site. For example, the enzyme *Eco*RI (named after its source strain of the bacterium *E. coli*) cuts DNA only where it encounters the following paired sequence in the DNA double helix:

5' . . . GAATTC . . . 3'

3' . . . CTTAAG . . . 5'

Note that this sequence is palindromic, like the word “mom.” This means that both strands have the same sequence when they are read from their 5' (or their 3') ends. The *Eco*RI enzyme has two identical active sites on its two subunits, which cleave the two strands simultaneously between the G and the A of each strand:

The *EcoRI* recognition sequence occurs, on average, about once in every 4,000 base pairs in a typical prokaryotic genome, or about once per four prokaryotic genes. So *EcoRI* can chop a large piece of DNA into smaller pieces containing, on average, just a few genes. Using *EcoRI* in the laboratory to cut small genomes, such as those of viruses that have tens of thousands of base pairs, may result in just a few fragments. For a huge eukaryotic chromosome with tens of millions of base pairs, a very large number of fragments will be created.

Of course, “on average” does not mean that the enzyme cuts all stretches of DNA at regular intervals. For example, the *EcoRI* recognition sequence does not occur even once in the 40,000 base pairs of the T7 bacteriophage genome—a fact that is crucial to the survival of this virus, since its host is *E. coli*. Fortunately for *E. coli*, the *EcoRI* recognition sequence does appear in the DNA of other bacteriophages.

Gel electrophoresis separates DNA fragments

Restriction enzyme digestion is used to manipulate DNA in the laboratory so that mutations can be identified and analyzed. After a laboratory sample of DNA has been cut with one or more restriction enzymes, the DNA is in fragments, which must be separated to identify (map) where the cuts were made. Because the recognition sequence does not occur at regular intervals, the fragments are not all the same size, and these size differences can be used to separate the fragments from one another. Separating the fragments is necessary to determine the number and molecular sizes (in base pairs) of the fragments produced, or to identify and purify an individual fragment for further analysis or for use in an experiment.

Gel electrophoresis is a common and convenient technique for separating or purifying DNA fragments. Samples containing the fragments are placed in wells at one end of a semisolid gel (usually made of agarose or polyacrylamide), and an electric field is applied to the gel ([Figure 15.12](#)). Because of its phosphate groups, DNA is negatively charged at neutral pH; therefore, because opposite charges attract, the DNA fragments move through the gel toward the positive end of the field. Because the spaces between the polymers of the gel are small, small DNA molecules can move through the gel faster than larger ones. Thus DNA fragments of different sizes separate from one another, forming bands that can be detected with a dye. This provides three types of information:

gel electrophoresis (e lek' tro fo ree' sis) [L. *electrum*: amber + Gk. *phorein*: to bear] A technique for separating molecules (such as DNA fragments) from one another on the basis of their electric charges and molecular weights by applying an electric field to a gel.

research tools

Figure 15.12 Separating Fragments of DNA by Gel Electrophoresis A mixture of DNA fragments is placed in a gel, and an electric field is applied across the gel. The negatively charged DNA moves toward the positive end of the field, with smaller molecules moving faster than larger ones. After minutes to hours for separation, the electric power is shut off and the separated fragments can be analyzed.

- *The number of fragments.* The number of fragments produced by digestion of a DNA sample with a given restriction enzyme depends on how many times that enzyme's recognition sequence occurs in the sample. Thus gel electrophoresis can provide some information about the presence of specific DNA sequences (the restriction sites) in the DNA sample.
- *The sizes of the fragments.* DNA fragments of known size (size markers) are often placed in one well of the gel to provide a standard for comparison. The size markers are used to determine the sizes of the DNA fragments in samples in the other wells. By comparing the fragment sizes obtained with two or more restriction enzymes, the locations of their recognition sites relative to one another can be worked out (mapped).
- *The relative abundance of a fragment.* In many experiments, the investigator is interested in how much DNA is present. The relative intensity of a band produced by a specific fragment can indicate the amount of that fragment.

DNA fingerprinting combines PCR with restriction analysis and electrophoresis

The methods we have just described are used in **DNA fingerprinting**, which identifies individuals based on differences in their DNA sequences. DNA fingerprinting works best with sequences that are highly polymorphic—that is, sequences that have multiple alleles (because of many point mutations during the evolution of the organism) and are therefore likely to be different in different individuals. Two types of polymorphisms are especially informative:

DNA fingerprint An individual's unique pattern of allele sequences, commonly short tandem repeats and single nucleotide polymorphisms.

- **Single nucleotide polymorphisms (SNPs)** (pronounced “snips”) are inherited variations involving a single nucleotide base—they are point mutations. These polymorphisms have been mapped for many organisms. If one parent is homozygous for the base A at a certain point in the genome, and the other parent is homozygous for a G at that point, the offspring will be heterozygous: one chromosome will have A at that point and the other will have G. If a SNP occurs in a restriction enzyme recognition site, such that one variant is recognized by the enzyme and the other isn't, then individuals can be distinguished from one another very easily using the ***polymerase chain reaction (PCR)**. A fragment containing the polymorphic sequence is amplified by PCR from samples of total DNA isolated from each individual. The fragments are then cut with the restriction enzyme and analyzed by gel electrophoresis.

Activity 15.3 **Allele-Specific Cleavage** www.Life11e.com/ac15.3

- **Short tandem repeats (STRs)** are short, repetitive DNA sequences that occur side by side on the chromosomes, usually in the noncoding regions. These repeat patterns, which contain one to five base pairs, are also inherited. For example, at a particular locus on chromosome 15 there may be an STR of “AGG.” An individual may inherit an allele with six copies of the repeat (AGGAGGAGGAGGAGGAGG) from her mother and an allele with two copies (AGGAGG) from her father. Again, PCR is used to amplify DNA fragments containing these repeated sequences, and then the amplified fragments, which have different sizes because of the different lengths of the repeats, are distinguished by gel electrophoresis (**Figure 15.13A**).

single nucleotide polymorphisms (SNPs) Inherited variations in a single nucleotide base in DNA that differ between individuals.

PCR See polymerase chain reaction.

short tandem repeats (STRs) Short (1–5 base pairs), moderately repetitive sequences of DNA. The number of copies of an STR at a particular location varies between individuals and is inherited.

(A) STR analysis compares sequence for specific loci from two or more DNA samples.

(B) DNA fingerprinting confirms individual's identities

Figure 15.13 DNA Fingerprinting with Short Tandem Repeats (A) A particular STR locus can be analyzed to determine the number of repeat sequences that were inherited by an individual from each parent. The two alleles can be identified in an electrophoresis gel on the basis of their sizes. When several STR loci are analyzed, the pattern can constitute a definitive identification of an individual. (B) When the dictator Saddam Hussein was captured in Iraq, a sample of his cheek epithelial cells was taken for DNA fingerprinting. A comparison with DNA fingerprints of relatives provided military scientists with evidence that the man in question was indeed

Saddam Hussein.

Q: Should everyone have their DNA fingerprinted at birth to create a “genetic ID” for use in screening for genetic diseases? What would be the advantages and disadvantages of this?

The method of DNA fingerprinting used most commonly today hydrolyzes STR analysis. The Federal Bureau of Investigation in the United States uses 13 STR loci in its Combined DNA Index System (CODIS) database ([Table 15.3](#)). An analysis of these loci in your DNA would reveal your particular DNA fingerprint. Looking at [Table 15.3](#), you might inherit:

table 15.3 Four of the Genetic Loci Used for Identification in the CODIS Database

Human chromosome	Locus name	Repeated sequence	Number of alleles
4	FGA	CTTT	80
7	D7S820	GATA	30
11	TH01	TCAT	20
18	S18S51	AGAA	51

From your mother: allele 72 from chromosome 4; allele 23 from chromosome 7; allele 14 from chromosome 11; and allele 12 from chromosome 18

From your father: allele 56 from chromosome 4; allele 22 from chromosome 7; allele 16 from chromosome 11; and allele 12 from chromosome 18

Note that in this case you are heterozygous for the alleles on three of the chromosomes and homozygous for the allele on chromosome 18. With all the alleles and 13 loci, the probability of two people sharing the same alleles is very small. So a DNA sample from a crime scene can be used to determine whether a particular suspect left that sample at the scene.

As we have just shown, DNA fingerprinting can be used to help prove the innocence or guilt of a suspect, but it can also be used to identify individuals who are related to one another. On May 2, 2011, Osama bin Laden was killed by U.S. soldiers at his home in Pakistan. He was identified at the scene by comparison with photographs, a wife who pointed him out, and instant analysis using a digital camera with facial recognition software. In addition, DNA fingerprinting was used. Bin Laden’s son Khalid was also killed in the raid, and a sister had previously died in the U.S. Analyses of their DNA along with that of Osama indicated that the three shared many polymorphisms and were highly likely to be closely related. The same methods were also used to identify Saddam Hussein, who was captured in 2003 and later executed in Iraq ([Figure 15.13B](#)).

DNA analysis with genetic markers such as SNPs and STRs has applications throughout all areas of biological research. For example, these markers are used to analyze the organization of genomes, to identify species or individuals within species, to compare species or organisms to see how closely related they are, and to analyze particular genes and the phenotypes associated with them. In the remainder of this chapter we will focus on the use of these markers and other technologies that are used to study and treat genetic diseases.

DNA analysis can be used to identify mutations that lead to disease

With diseases such as PKU and sickle-cell anemia, you have seen that the clinical phenotypes of inherited diseases could be traced to individual proteins, and that the genes could then be identified. For example, in sickle-cell anemia, the protein abnormality in hemoglobin was described first (a single amino acid change), and then the gene for β -globin was isolated and the DNA mutation was pinpointed.

Clinical phenotype → protein phenotype → gene

With the advent of new ways to identify DNA variations, a new pattern of human genetic analysis emerged. In these cases, the clinical phenotype is first related to a DNA variation, and then the gene and protein involved are identified. For cystic fibrosis (see [Table 15.2](#)), a mutant version of the gene *CFTR* was isolated first, and then the protein was characterized:

Clinical phenotype → gene → protein phenotype

Whichever approach is used, final identification of the protein(s) involved in a disease is important in designing specific therapies.

Genetic markers can be used to find disease-causing genes

Identifying a mutant gene requires finding a marker that is closely linked to the gene of interest, a process called [linkage analysis](#). The reference points for gene isolation are [genetic markers](#). Genetic markers such as STRs and SNPs can be used as landmarks to find a gene of interest, if the gene also has multiple alleles (for example, normal and disease-causing alleles). The key to this method is the well-established observation that if two genes are located near each other on the same chromosome, they are usually passed on together from parent to offspring (see [Key Concept 12.4](#)). The same holds true for any pair of DNA genetic markers. In the case of linkage analysis, the idea is to find markers that are progressively closer to the gene of interest.

linkage analysis Genetic analysis in which a gene and its alleles are linked to an unknown gene and its alleles and the location of the latter is determined by its co-segregating with the former in genetic crosses.

genetic marker (1) In gene cloning, a gene of identifiable phenotype that indicates the presence of another gene, DNA segment, or chromosome fragment. (2) In general, a DNA sequence such as a single nucleotide polymorphism whose presence is correlated with the presence of other linked genes on that chromosome.

As you have seen, SNPs and STRs are widespread in eukaryotic genomes. There is roughly one SNP for every 1,330 base pairs in the human genome, and any regions of the genome also contain repetitive DNA sequences such as those found in STRs. SNPs and STRs can be analyzed using the PCR techniques mentioned above. SNPs can also be detected using sophisticated chemical methods such as mass spectrometry.

To narrow down the location of a gene, a scientist must find a genetic marker that is *always inherited with the gene*. To do this, family medical histories are taken and pedigrees are constructed. If a genetic marker and a genetic disease are inherited together in many families, then they must be near each other on the same chromosome ([Figure 15.14](#)). This situation recalls the conclusion reached in the classic studies of inheritance undertaken by Thomas Hunt Morgan and discussed in [Key Concept 12.4](#): two genes do not always assort independently. Genes that are “linked” on the same chromosome will sometimes be inherited together—especially when the two loci are close to one another on the chromosome.

Figure 15.14 DNA Linkage Analysis Linkage of an SNP to a disease-causing allele in many families narrows down the location of the defective gene, making its isolation and identification possible. In the example shown here, the disease-causing allele is recessive.

Q: How is DNA linkage analysis similar to chromosome linkage analysis in genetics? How is it different?

Linkage narrows down the location of the gene to a few hundred thousand base pairs. Once a linked DNA region is identified, many methods are available to identify the actual gene responsible for a genetic disease. The complete sequence of the region can be searched for candidate genes, using information available from databases of genome sequences. With luck a scientist can make an educated guess, based on biochemical or physiological information about the disease, along with information about the functions of candidate genes, as to which gene is responsible for the disease. The identification of DNA polymorphisms within candidate genes that correlate with the presence or absence of disease can also help narrow down the search. A variety of techniques, such as analyzing mRNA levels of candidate genes in diseased and healthy individuals, are used to confirm that the correct gene has been identified.

The isolation of the *BRCA1* gene that is involved in breast cancer (described in the chapter opening) offers a good illustration of molecular techniques used to identify genes associated with disease, and is described in **Investigating Life: How Was the *BRCA1* Gene Identified?** Analysis of the *BRCA1* mutations came after Marie-Claire King of the University of California at Berkeley worked with breast cancer patients and their families to identify SNPs closely linked to the breast cancer phenotype.

investigatinglife
Gene Identified?

How Was the *BRCA1*

experiment

Original Paper: Miki, Y. et al. 1994. A strong candidate for the breast and ovarian cancer susceptibility gene *BRCA1*. *Science* 266: 66–71.

DNA linkage analysis of families led to the isolation of *BRCA1*, a gene that can lead to breast cancer.

HYPOTHESIS ▶ A gene mutated in hereditary breast cancer can be isolated.

METHOD

RESULTS

CONCLUSION ▶ The *BRCA1* gene is mutated in people with hereditary breast cancer.

work with the data

About one in ten cases of breast cancer is hereditary. That is, the cancer arises from a germ line mutation (meaning it occurs in all cells of the body) that is expressed in breast cells as cancer. The other nine in ten cases come about from somatic mutations in breast cells. The identification of a gene involved in hereditary breast cancer was made by DNA analysis. First, the location of the gene was narrowed down by analysis of SNPs in families where several women had breast cancer (see the experiment). Then a team led by Mark Skolnick at the University of Utah and the company Myriad Genetics sequenced the DNA in the candidate region and looked for a sequence that had a promoter, transcription terminator, start and stop codons, and sequences at the ends of introns—in short, the sequences that mark a protein-coding gene. Once they found the candidate gene, they subjected it to a series of tests to see if it was the one associated with breast cancer.

QUESTIONS

1. Hereditary (as opposed to somatic) breast cancer is often suspected when the cancer develops relatively early in life. Hereditary cancers tend to arise earlier because they involve a germ line mutation present in all cells at birth, whereas a cancer due to a spontaneous somatic mutation in the DNA of a breast cell can happen any time (statistically, later). Skolnick's team examined the timing of breast cancer cases in patients who had different mutations in *BRCA1*. The results are shown in **Table A**. What conclusions can you draw?

Table A

Family	Total cases	Cases before age 50
A	31	20
B	22	14
C	10	7

2. DNA sequencing evaluated *BRCA1* in the cancer patients and their families, as well as in controls who did not have breast cancer themselves or in their family. The results are shown in **Table B**. Were the mutations in *BRCA1* present only in the breast cancer patients? What do you think the effects of the mutations were in each of the three families?

Table B

Family	Codon number in <i>BRCA1</i>	Change in patients	Change in controls?
A	1313	C → T	None (0/170)
B	1775	T → G	None (0/120)
C	24	deletion 11 bp	None (0/180)

3. Human tissues from people without breast cancer were examined by nucleic acid hybridization (see Figure 14.6) for the level of mRNA for *BRCA1*. The results are shown in **Table C**. What can you conclude about the kinds of cancer that might be caused by mutations in *BRCA1*?

Table C

Tissue	mRNA detected?
Breast	Yes
Colon	No
Intestine	No
Ovary	Yes
Prostate	No
Spleen	No
Testis	No
Thymus	Yes

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Large DNA molecules can be cut into smaller pieces by restriction digestion and then sorted by gel electrophoresis. PCR is used to amplify sequences of interest from complex samples. These techniques are used in DNA fingerprinting to analyze DNA polymorphisms for the purpose of identifying individuals. Genes involved in disease can be identified by first detecting the abnormal DNA sequence and then the protein that the wild-type allele encodes. Scientists hope to be able to identify all species using DNA analysis.

learning outcomes

You should be able to:

- Explain how DNA sequencing can be used to identify mutations.
- Explain how a mutation can be identified as a cause for disease.

-
1. Cystic fibrosis is an autosomal recessive disease in which thick mucus is produced in the lungs and airways. The gene responsible for this disease encodes a protein composed of 1,480 amino acids. In most patients with cystic fibrosis, the protein has 1,479 amino acids: a phenylalanine is missing at position 508. A baby is born with cystic fibrosis. He has an older brother who is not affected. How would you test the DNA of the older brother to determine whether he is a carrier for cystic fibrosis?
 2. How can a gene mutation that causes a disease be mapped and detected before its protein product is known?

The determination of the precise molecular phenotypes and genotypes of various human genetic diseases has made it possible to diagnose these diseases even before symptoms appear. Let's take a detailed look at some of these genetic screening techniques.

* **connect the concepts** As described in [Key Concept 13.5](#), PCR is a technique used to make multiple copies of a DNA sequence—that is, to amplify it. The process essentially automates DNA replication; over many cycles the amount of DNA can be increased exponentially.

15.4 Genetic Screening Is Used to Detect Diseases

Genetic screening is the use of a test to identify people who have, are predisposed to, or are carriers of a genetic disease. It can be done at many times of life and used for many purposes:

genetic screen A technique for identifying genes involved in a biological process of interest. Involves creating a large collection of randomly mutated organisms and identifying those individuals that are likely to have a defect in the pathway of interest. The mutated gene(s) in those individuals can then be isolated for further study.

Prenatal screening can be used to identify an embryo or fetus with a disease so that medical intervention can be applied or decisions can be made about whether or not to continue the pregnancy.

Newborn babies can be screened so that proper medical intervention can be initiated quickly for those babies who need it.

Asymptomatic people who have relatives with a genetic disease can be screened to determine whether they are carriers of the disease-associated allele or are likely to develop the disease themselves.

Genetic screening can be done at the level of either the phenotype or the genotype.

focus your learning

Genetic screening can involve phenotype or genotype analysis.

Genetic screening can be done by examining the phenotype

Genetic screening can involve examining a protein or other chemical that is relevant to a phenotype associated with a particular disease. Perhaps the best example is the test for phenylketonuria (PKU), which has made it possible to identify the disease in newborns, so that treatment can be started immediately. It is very likely that you were screened as a newborn for PKU.

Initially, babies born with PKU have a normal phenotype because excess phenylalanine in their blood before birth diffuses across the placenta to the mother's circulatory system. Since the mother is almost always heterozygous, and therefore has adequate phenylalanine hydroxylase activity, her body metabolizes the excess phenylalanine from the fetus. After birth, however, the baby begins to consume protein-rich food (milk) and to break down some of his or her own proteins. Phenylalanine begins to accumulate in the blood. After a few days, the phenylalanine level in the baby's blood may be ten times higher than normal. Within days, the developing brain is damaged, and untreated children with PKU become severely intellectually disabled. But if detected early, PKU can be treated with a special diet low in phenylalanine to avoid the brain damage that would otherwise result. Thus early detection is imperative.

Routine newborn screening for PKU and other diseases began in 1963 with the development of a simple, rapid test for the presence of excess phenylalanine in blood serum ([Figure 15.15](#)). This method uses dried blood spots from newborn babies and can be automated so that a

screening laboratory can process many samples in a day. Newborn babies' blood is now screened for up to 35 genetic diseases. Some are common, such as congenital hypothyroidism, which occurs about once in 4,000 births and causes reduced growth and intellectual disability because of low levels of thyroid hormone. With early intervention, many of these infants can be successfully treated. So it is not surprising that newborn screening is legally mandatory in many countries, including the United States and Canada. You were probably screened for several genetic diseases in the first days of your life. Ask your parents which ones!

Figure 15.15 Genetic Screening of Newborns for Phenylketonuria A blood test is used to screen newborns for phenylketonuria. Small samples of blood are taken from a newborn's heel. The samples are placed in a machine that measures the phenylalanine concentration in the blood. Early detection means that the symptoms of the condition can be prevented by putting the baby on a therapeutic diet.

DNA testing is the most accurate way to detect abnormal genes

The level of phenylalanine in the blood is an indirect measure of phenylalanine hydroxylase activity in the liver. But how can we screen for *genetic diseases that are not detectable by blood tests? What if blood is difficult to obtain, as it is in a fetus? How are genetic abnormalities in heterozygotes, who express the normal protein at some level, identified?

DNA testing is the direct analysis of DNA for a mutation, and it offers the most direct and accurate way of detecting an abnormal allele. Now that the mutations responsible for many human diseases have been identified, any cell in the body can be examined at any time of life for mutations. The amplification power of PCR means that only one or a few cells are needed for testing. These methods work best for diseases caused by only one or a few different mutations.

DNA testing In human genetics, the determination of genotype by analysis of DNA sequence.

Consider, for example, two parents who are both heterozygous for the cystic fibrosis allele but who want to have a healthy child. If treated with the appropriate hormones, the mother can be induced to “superovulate,” releasing several eggs. Eggs can be harvested from the mother and artificially inseminated. The fertilized egg can be allowed to divide to the eight-cell stage. If one of these embryonic cells is removed, it can be tested for the presence of the cystic fibrosis allele. If the test is negative, the remaining seven-cell embryo can be implanted in the mother's womb, where with luck it will develop normally.

Such preimplantation screening is performed only rarely. More typical are analyses of fetal cells after normal fertilization and implantation in the womb. Fetal cells or even DNA that has

leaked out of dead cells can be analyzed at about the tenth week of pregnancy by chorionic villus sampling, or during the thirteenth to seventeenth weeks by amniocentesis. In either case, only a few fetal cells are necessary to perform DNA testing. Recently, very sensitive methods were developed so that DNA testing can be done with the few fetal cells that are released into the mother's blood. A 10-milliliter blood sample from a pregnant woman has enough fetal cells for the analysis of many disorders, including Down syndrome and cystic fibrosis. This relatively noninvasive procedure could replace amniocentesis and chorionic villus sampling—which both carry a slight risk of causing a miscarriage—in the near future.

DNA testing can also be performed with newborns. The blood samples used for screening for PKU and other disorders contain enough of the baby's blood cells to permit DNA analysis using PCR-based techniques. DNA analysis is now being used to screen for sickle-cell disease and cystic fibrosis; similar tests for other diseases will surely follow. Of the numerous methods of DNA testing available, we will describe DNA hybridization, using sickle-cell anemia as an example.

Allele-specific oligonucleotide hybridization can detect mutations

Nucleic acid hybridization (see [Figure 14.6](#)) can be used to detect the presence of a specific DNA sequence, such as a sequence containing a particular mutation. Samples of DNA are collected from people who may or may not carry the mutation, and PCR is used to amplify the region of DNA where the mutation may occur. Short synthetic DNA strands called oligonucleotide probes are hybridized with the denatured PCR products. The probe is labeled in some way (e.g., with radioactivity or a fluorescent dye) so that hybridization can be readily detected ([Figure 15.16](#)).

Figure 15.16 DNA Testing by Allele-Specific Oligonucleotide Hybridization Testing of this family reveals that three of them are heterozygous carriers of the sickle allele. The first child, however, has inherited two normal alleles and is neither affected by the disease nor a carrier.

Animation 15.2 DNA Testing www.Life11e.com/a15.2

Detection of a mutation by DNA screening can be used for diagnosis of a genetic disease, so that appropriate treatment can begin. In addition, DNA screening provides a person with important information about his or her genome.

15.4 recap

Genetic screening can be used to identify people who have, are predisposed to, or are carriers of genetic diseases. Screening can be done at the phenotype level by identifying an abnormal protein such as an enzyme with altered activity. It can also be done at the

genotype level by direct testing of DNA.

learning outcomes

You should be able to:

- Compare and contrast phenotypic and genotypic genetic screening.
 - Explain how DNA testing is used for genetic screening.
-
1. What is the advantage of screening for genetic mutations by allele-specific oligonucleotide hybridization relative to screening phenotype differences in enzyme activity?
 2. Explain how allele-specific oligonucleotide hybridization could be used to do genetic screening for sickle-cell anemia.

Ongoing research has resulted in the development of increasingly accurate diagnostic tests and a better understanding of various genetic diseases at the molecular level. This knowledge is now being applied to the development of new treatments for genetic diseases. In the next section we will survey various approaches to treatment, including modifications of the mutant phenotype and gene therapy, in which the normal version of a mutant gene is supplied.

***connect the concepts** Genetic testing is a rapidly changing field, with tests being done at different stages of prenatal development. See [Key Concept 43.2](#) for an overview of the stages of human development, to place the timing of genetic tests in perspective.

15.5 Genetic Diseases Can Be Treated

Most treatments for genetic diseases simply try to alleviate the patient's symptoms. But to effectively treat these diseases—whether they affect all cells, as in inherited disorders such as PKU, or only somatic cells, as in cancer—physicians must be able to diagnose the disease accurately, understand how the disease works at the molecular level, and intervene early, before the disease ravages or kills the individual. There are two main approaches to treating genetic diseases:

- . Modifying the disease phenotype
- . Replacing the defective gene (modifying the genotype)

focus your learning

Some genetic diseases are treated at the phenotype level.

Other genetic diseases can be treated at the level of the gene using gene therapy.

Genetic diseases can be treated by modifying the phenotype

Altering the phenotype of a genetic disease so that it no longer harms an individual is commonly done in one of three ways: by restricting the substrate of a deficient enzyme, by inhibiting a harmful metabolic reaction, or by supplying a missing protein product ([Figure 15.17](#)).

Figure 15.17 Strategies for Treating Genetic Diseases

RESTRICTING THE SUBSTRATE

Restricting the substrate of a deficient enzyme is the approach taken when a newborn is diagnosed with PKU. In this case, the deficient enzyme is phenylalanine hydroxylase, and the substrate is phenylalanine (see [Figure 15.6](#)). The infant's inability to break down phenylalanine in food leads to a buildup of the substrate, which causes the clinical symptoms. So the infant is immediately put on a special diet that contains only enough phenylalanine for immediate use. Lofenelac, a milk-based product that is low in phenylalanine, is fed to these infants just like formula. Later, certain fruits, vegetables, cereals, and noodles low in phenylalanine can be added to the diet. Meat, fish, eggs, dairy products, and bread, which contain high amounts of phenylalanine, must be avoided, especially during childhood, when brain development is most rapid. The artificial sweetener aspartame must also be avoided because it is made of two amino acids, one of which is phenylalanine.

People with PKU are generally advised to stay on a low-phenylalanine diet for life. Although maintaining these dietary restrictions may be difficult, it is effective. Numerous follow-up studies

since newborn screening was initiated have shown that people with PKU who stay on the diet are no different from the rest of the population in terms of mental ability. This is an impressive achievement in public health, given the severity of intellectual disability in untreated patients.

METABOLIC INHIBITORS

In [Key Concept 11.7](#) we described how drugs that are inhibitors of various cell cycle processes are used to treat cancer. Drugs are also used to treat the symptoms of many genetic diseases. As biologists have gained insight into the molecular characteristics of these diseases and the specific proteins involved, a more specific approach to treatment is taking shape. Targeted therapies are being developed, especially for cancer, and some have resulted in life-saving interventions. This is a major area of applied research.

SUPPLYING THE MISSING PROTEIN

An obvious way to treat a disease caused by the lack of a functional protein is to supply that protein. This approach is used to treat hemophilia A, a disease in which blood factor VIII is missing and blood clotting is impaired (see [Table 15.2](#)). In the past, the missing protein was obtained from blood. Sometimes, however, blood carries contaminants, such as viruses (e.g., HIV) or other pathogens that could harm the recipient. Now human clotting proteins are produced by recombinant DNA technology (see [Chapter 18](#)), making it possible to provide the protein in a much purer form.

Unfortunately, the phenotypes of many diseases caused by genetic mutations are very complex. In these cases, simple interventions like those we have just described do not work. Indeed, a recent survey of 351 diseases caused by single-gene mutations showed that current therapies increased patients' life spans by an average of only 15 percent.

Gene therapy offers the hope of specific treatments

If a cell lacks an allele that encodes a functional product, an optimal treatment would be to provide a functional allele. The objective of [gene therapy](#) is to add a new gene that will be expressed in appropriate cells in a patient. What cells should be targeted? There are two approaches:

gene therapy Treatment of a genetic disease by providing patients with cells containing functioning alleles of the genes that are nonfunctional in their bodies.

- [Germ line gene therapy](#): The new gene is inserted into a gamete (usually an egg) or the fertilized egg. In this case, all cells of the adult will carry the new gene. Ethical considerations preclude the use of this method in humans.
- [Somatic cell gene therapy](#): The new gene is inserted into somatic cells involved in the disease. This method is being tried for numerous diseases, ranging from inherited genetic disorders to cancer.

germ line gene therapy Alteration of the human genome sequence in the gametes or cells giving rise to gametes for medical benefit. (Contrast with somatic cell gene therapy.)

somatic cell gene therapy Alteration of the human genome sequence in somatic cells for medical benefit. (Contrast with germ line gene therapy.)

There are two approaches to somatic cell gene therapy:

- [Ex vivo gene therapy](#): Target cells are removed from the patient, given the new gene, and

then reinserted into the patient. This approach is being used, for example, for diseases caused by defects in genes that are expressed in white blood cells.

In vivo gene therapy: The gene is actually inserted directly into a patient, targeted to the appropriate cells. An example is a treatment for lung cancer in which a solution with a therapeutic gene is squirted onto a tumor.

ex vivo gene therapy Alteration of the human genome sequence in the cells removed from the body and then reimplanted into the body for medical benefit.

in vivo gene therapy Alteration of the human genome sequence in cells in the body for medical benefit.

Armed with knowledge of how genes are expressed (see [Chapter 14](#)) and regulated (see [Chapter 16](#)), physicians can design a therapeutic gene that contains not only a normal protein-coding sequence but also other sequences—such as an appropriate promoter—required for the gene's expression in targeted cells.

A major challenge has been getting the therapeutic gene into cells. Uptake of DNA into eukaryotic cells is a rare event, and once the DNA is inside a cell, its entry into the nucleus and expression are rarer still. One solution to these problems is to insert the gene into a carrier virus (a viral vector) that can infect human cells but has been altered genetically to prevent viral replication. An example is the DNA virus called [adeno-associated virus](#), which has been widely used in human gene therapy clinical trials. This virus has a small genome that can be spliced into a human gene; infects most human cells, including nondividing cells such as neurons; is harmless to humans; does not provoke rejection by the immune system; and enters the cell nucleus, where its DNA with the new gene can be expressed.

adeno-associated virus A small, non-pathogenic virus with a single-strand DNA genome, that can be used for gene therapy in humans and does not integrate unto the host chromosomes.

Adeno-associated virus has been used successfully in human gene therapy targeting Parkinson's disease ([Figure 15.18](#)). Parkinson's disease is a neurological condition that affects about 1 in 200 persons in their 60s, and 1 in 25 persons in their 80s. Its symptoms include muscle stiffness and shaking and—in about half of the patients—dementia. Patients with Parkinson's disease produce inadequate amounts of the neurotransmitter γ -aminobutyric acid (GABA) in a particular part of the brain due to degeneration of the neurons that normally produce GABA. Low GABA levels result in poor coordination of movement. Raising GABA levels would thus be a reasonable approach to treatment. Recognizing that synthesis of GABA is catalyzed by the enzyme glutamate decarboxylase, a team led by Dr. Andrew Feigin at the Feinstein Institute in New York packaged a glutamate decarboxylase gene into adeno-associated virus that was then injected into the affected part of the brain. After six months, the patients who received the virus-encapsulated gene had increased levels of GABA and significant improvement in their disease symptoms. Other diseases being treated with gene therapy using this virus include cystic fibrosis, hemophilia, and muscular dystrophy. While this looks exciting on paper, bear in mind that this type of therapy is very rare, at the frontier of medicine. We aren't close to the day when we can go see our local gene therapist for a cure.

Figure 15.18 Gene Therapy

Original Paper: LeWitt, P. A. et al. 2011. AAV2-GAD gene therapy for advanced Parkinson's disease: A double-blind, sham-surgery controlled randomized trial. *Lancet Neurology* 10: 309–319.

Andrew Feigin and his colleagues showed that a virus can be used to insert a therapeutic gene into the brains of patients with Parkinson's disease.

HYPOTHESIS ▶ Adding a gene for glutamate decarboxylase to brain cells can alleviate symptoms caused by GABA deficiency.

- 1 A gene for glutamate decarboxylase is inserted into the genome of adeno-associated virus.

RESULTS The patient's symptoms improved.

CONCLUSION ▶ Gene therapy can relieve symptoms in a patient with a neurotransmitter deficiency.

A **work with the data** exercise that accompanies this figure may be assigned in **LaunchPad**.

15.5 recap

Treatment of a human genetic disease may involve an attempt to modify the abnormal

phenotype by restricting the substrate of a deficient enzyme, inhibiting a harmful metabolic reaction, or supplying a missing protein. By contrast, gene therapy aims to address a genetic defect by inserting a normal allele into a patient's cells.

learning outcomes

You should be able to:

- Explain how a genetic disease can be treated by modifying the disease phenotype.
 - Compare ex vivo and in vivo approaches to gene therapy.
-

1. How do metabolic inhibitors function in treating genetic diseases such as cancer?
 2. How does in vivo gene therapy work? Can you give an example?
 3. In the past, it was common for people with phenylketonuria (PKU) who were placed on a low-phenylalanine diet after birth to be allowed to return to a normal diet during their teenage years. Although the levels of phenylalanine in their blood were high, their brains were thought to be beyond the stage when they could be harmed. If a woman with PKU becomes pregnant, however, a problem arises. Typically, the fetus is heterozygous but is unable, at early stages of development, to metabolize the high levels of phenylalanine that arrive from the mother's blood.
 - a. Why is the fetus likely to be heterozygous?
 - b. What do you think would happen to the fetus during this "maternal PKU" situation?
 - c. What would be your advice to a woman with PKU who wants to have a child?
-

In this chapter you have learned about mutations, focusing on DNA changes that affect phenotypes through specific protein products. But there is much more to molecular genetics than the sequences of genes and proteins. Determining which genes will be expressed when and where is a major function of the genome. In [Chapter 16](#) we will turn to gene regulation.

investigatinglife

What is the breast cancer gene, and what are the issues with DNA testing for cancer?

Angelina Jolie's public announcement that she had elected to have her breasts removed in light of her cancer gene mutations attracted worldwide interest. In fact, the phrase "mutation" had never been so popular on internet search engines! Requests for *BRCA1* testing from worried women have increased dramatically. Two issues have arisen: who should be tested, and who should perform the test? Because breast cancer is relatively common (women have about a 10 percent lifetime chance of having it), having several relatives who have had the disease is not unusual. Medical geneticists have come up with several criteria for defining when *BRCA1* DNA analysis is warranted. These include having several close relatives who had or have the disease, with early onset (typically before age 50) and the presence of multiple tumors.

Even when a test shows no *BRCA1* mutations in a woman with a family history of breast or ovarian cancer, we cannot say that breast or ovarian cancer may not arise. It turns out that *BRCA1* mutations only account for about one in five hereditary breast cancer cases. Other genes are involved; we just don't know what they are, so we can't analyze their DNA. Remember: hereditary breast cancer (a germ line mutation) accounts for only one case in ten. The other 90 percent arise from somatic mutation of breast cells.

As to who does the test, the *BRCA1* gene was isolated by a private company that patented the DNA sequence. Until recently, that company was the only lab that could do *BRCA1* analysis, and not surprisingly, the price was high. In 2013, the U.S. Supreme Court invalidated the patent, and now more labs can do it, and more cheaply.

Future directions

Are there genetic tests for other hereditary cancers? About 10 percent of all cancers are caused by inheritance of mutated oncogenes or tumor suppressor genes (as opposed to mutations that occur after birth). As with the situation in breast cancer, a person who inherits a cancer-causing mutation has a much higher chance of developing cancer than one who does not have that mutation. As whole genome DNA sequencing is developed (see [Chapter 18](#)), mutations involved with other types of hereditary cancer are being identified and screening of relatives with a propensity for cancer is on the horizon.

► 15.1 Mutations Are Heritable Changes in DNA

- **Mutations** are stable, heritable changes in DNA. **Somatic mutations** are passed on to daughter cells, but only **germ line mutations** are passed on to sexually produced offspring. **Review Focus: Key Figure 15.1, Activity 15.1, Activity 15.2**

mutation A change in the genetic material not caused by recombination.

somatic mutation Permanent genetic change in a somatic cell (as opposed to a germ cell, the egg or sperm). These mutations affect the individual only; they are not passed on to offspring. (Contrast with germ line mutation.)

germ line mutation Mutation in a cell that produces gametes (i.e., a germ line cell). (Contrast with somatic mutation.)

- **Point mutations** result from alterations in single base pairs of DNA. **Silent mutations** can occur in noncoding DNA or in coding regions of genes and do not affect the amino acid sequences of proteins. **Missense, nonsense, and frame-shift mutations** all cause changes in protein sequences. **Review Figure 15.2**

point mutation A mutation that results from the gain, loss, or substitution of a single nucleotide. (Contrast with deletion, duplication.)

silent mutation A change in a gene's sequence that has no effect on the amino acid sequence of a protein either because it occurs in noncoding DNA or because it does not change the amino acid specified by the corresponding codon. (Contrast with frame-shift mutation, missense mutation, nonsense mutation.)

frame-shift mutation The addition or deletion of a single or two adjacent nucleotides in a gene's sequence. Results in the misreading of mRNA during translation and the production of a nonfunctional protein. (Contrast with missense mutation, nonsense mutation, silent mutation.)

- Chromosomal mutations (**deletions, duplications, inversions, and translocations**) involve large regions of chromosomes. **Review Figure 15.3**

translocation (1) In genetics, a rare mutational event that moves a portion of a chromosome to a new location, generally on a nonhomologous chromosome. (2) In vascular plants, movement of solutes in the phloem.

- **Spontaneous mutations** occur because of instabilities in DNA or chromosomes. **Induced mutations** occur when a mutagen damages DNA. **Review Figure 15.4**

spontaneous mutation A genetic change caused by internal cellular mechanisms, such as an error in DNA replication. (Contrast with induced mutation.)

induced mutation A mutation resulting from exposure to a mutagen from outside the cell. (Contrast with spontaneous mutation.)

- Mutations can occur in “hot spots” where cytosine has been methylated to 5-methylcytosine. **Review Figure 15.5**
- Mutations, although often detrimental to an individual organism, are the raw material of evolution.

▶ 15.2 Mutations in Humans Can Lead to Diseases

- Abnormalities in proteins have been implicated in genetic diseases.
- While a single amino acid difference can be the cause of disease, amino acid variations have been detected in many functional proteins. **Review Figures 15.6, 15.7**
- Point mutations, deletions, and chromosome abnormalities are associated with genetic diseases. **Review Figure 15.8**
- The effects of fragile-X syndrome worsen with each generation. This pattern is the result of an **expanding triplet repeat**. **Review Figure 15.9**

expanding triplet repeat A three-base-pair sequence in a human gene that is unstable and can be repeated a few to hundreds of times. Often, the more the repeats, the less the activity of the gene involved. Expanding triplet repeats occur in some human diseases such as Huntington’s disease and fragile-X syndrome.

- A series of genetic mutations can lead to colon cancer. **Review Figure 15.10**
- **Multifactorial** diseases are caused by the interactions of many genes and proteins with the environment. They are much more common than diseases caused by mutations in a single gene.

multifactorial The interaction of many genes and proteins with one or more factors in the environment. For example, cancer is a disease with multifactorial causes.

▶ 15.3 Mutations Can Be Detected and Analyzed

- **Restriction enzymes**, which are made by microorganisms as a defense against viruses, bind to and cut DNA at specific **recognition sequences** (also called **restriction sites**), producing smaller fragments of DNA. This cutting process is known as **restriction digestion**. Restriction enzymes can be used in the laboratory to produce small fragments of DNA for study. **Review Figure 15.11**

restriction enzyme Any of a type of enzyme that cleaves double-stranded DNA at specific sites; extensively used in recombinant DNA technology. Also called a restriction endonuclease.

recognition sequence See restriction site.

restriction site A specific DNA base sequence that is recognized and acted on by a restriction endonuclease.

restriction digestion An enzymatic reaction in which a molecule of DNA is fully cleaved by a restriction enzyme.

- DNA fragments can be separated by size using **gel electrophoresis**. **Review Figure 15.12, Animation 15.1**

gel electrophoresis (e lek' tro fo ree' sis) [L. *electrum*: amber + Gk. *phorein*: to bear] A technique for separating molecules (such as DNA fragments) from one another on the basis of their electric charges and molecular weights by applying an electric field to a gel.

- **DNA fingerprinting** is used to distinguish among specific individuals or to reveal which individuals are most closely related to one another. It involves the detection of DNA polymorphisms, including **single nucleotide polymorphisms (SNPs)** and **short tandem repeats (STRs)**. **Review Figure 15.13, Activity 15.3**

DNA fingerprint An individual's unique pattern of allele sequences, commonly short tandem repeats and single nucleotide polymorphisms.

single nucleotide polymorphisms (SNPs) Inherited variations in a single nucleotide base in DNA that differ between individuals.

short tandem repeats (STRs) Short (1–5 base pairs), moderately repetitive sequences of DNA. The number of copies of an STR at a particular location varies between individuals and is inherited.

- It is possible to isolate both the mutant genes and the abnormal proteins responsible for human diseases. **Review Figure 15.14, Investigating Life: How Was the BRCA1 Gene Identified?**

► 15.4 Genetic Screening Is Used to Detect Diseases

- **Genetic screening** is used to detect human genetic diseases, alleles predisposing people to those diseases, or carriers of those disease alleles.

genetic screen A technique for identifying genes involved in a biological process of interest. Involves creating a large collection of randomly mutated organisms and identifying those individuals that are likely to have a defect in the pathway of interest. The mutated gene(s) in those individuals can then be isolated for further study.

- Genetic screening can be done by looking for abnormal protein expression. **Review Figure 15.15**
- **DNA testing** is the direct identification of mutant alleles. Any cell can be tested at any time in the life cycle. **Review Figure 15.16, Animation 15.2**

DNA testing In human genetics, the determination of genotype by analysis of DNA sequence.

► 15.5 Genetic Screening Is Used to Detect Diseases

- There are three ways to modify the phenotype of a genetic disease: restrict the substrate of a deficient enzyme, inhibit a harmful metabolic reaction, or supply a missing protein. **Review Figure 15.17**
- Cancer sometimes can be treated with metabolic inhibitors.
- In gene therapy, a mutant gene is replaced with a normal gene. Both ex vivo and in vivo therapies are being developed. **Review Figure 15.18**

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify

your understanding of this chapter. **LearningCurve** adapts to your responses, giving you the practice you need to master each key concept.

► Apply What You've Learned

Review

- 5.1 Use a defined DNA sequence to illustrate how the following occur and describe their effect upon phenotype: transitions, transversions, missense mutations, nonsense mutations, frame-shift mutations, and mutations outside the coding region of a gene.
- 5.2 Genetic diseases often result from mutations that render proteins nonfunctional.
- 5.2 Mutations that cause disease include the full range of affected DNA from point mutations to entire chromosomes.

Hemoglobin, composed of four polypeptide subunits and an oxygen-binding heme group, carries O_2 in human blood, delivering it to tissues. Because of the importance of O_2 for cellular respiration, a genetic mutation that alters the structure and function of hemoglobin can have severe consequences. In an adult, hemoglobin has two types of polypeptide subunits: alpha-globin (α -globin), consisting of 141 amino acids, and beta-globin (β -globin), consisting of 146 amino acids (see figure below).

People with thalassemia typically make little to no α - or β -globin and so have anemia—inadequate quantities of normal red blood cells. They need blood transfusions to survive. Most common in Mediterranean countries, thalassemia is typically inherited as an autosomal recessive. While homozygotes with the mutant alleles have severe symptoms, people who are heterozygous carriers for thalassemia often have mild anemia, as they have only one of two functional alleles for the globin gene in question.

Consider the following scenario: Two people have a mild, persistent anemia. Because each has relatives who suffered from thalassemia, they are concerned that they may be carriers for a thalassemia mutation. Tissue samples of both people are taken and DNA for globin genes sequenced. Here is a region for the normal β -globin gene in the coding strand of DNA:

Codon #	36	37	38	39	40	41
Normal:	CCT	TGG	ACC	CAG	AGG	TTC

Below are the DNA sequences of the coding strands for the same region of the β -globin gene in the two people with mild anemia. Person 1 has two different sequences in this region:

Sequence 1:	CCT	TGG	ACC	CAG	AGG	TTC
Sequence 2:	CCT	TGG	ACC	TAG	AGG	TTC

Person 2 also has two different sequences in this region:

Sequence 1:	CCT	TGG	ACC	CAG	AGG	TTC
Sequence 2:	CCT	GGA	CCC	AGA	GGT	TCT

Questions

1. Analyze the DNA sequences to identify the type of mutation (silent, nonsense, missense, or frame-shift) in these two patients. Then evaluate each mutation's effect on the protein chain.
2. Describe a mutation that would have an effect similar to that of the two mutations described but that would involve a change outside the coding region for the β -globin gene.
3. If person 1 were to have a child with person 2, what are the risks involved for this couple's children? Draw a pedigree chart to illustrate the possible outcomes.

[6.3 Viruses Regulate Their Gene Expression during the Reproductive Cycle](#)

investigatinglife

Gene Expression and Behavior

Any teenager or parent of a teenager will tell you that those years can be rough. But some young people have a rougher time than others. Teens whose mothers were extremely stressed during pregnancy often have more behavioral problems than those whose mothers had calmer pregnancies. A recent study led by psychologist Thomas Elbert and evolutionary biologist Axel Meyer at the University of Konstanz in Germany suggests an underlying genetic cause for these behavioral differences. The study examined a gene for the glucocorticoid receptor, which is involved in regulating hormonal responses to stress. The researchers found that teenagers whose mothers had suffered physical abuse during pregnancy had higher rates of cytosine methylation in the promoter of this gene than did teenagers whose mothers had not suffered such abuse.

A major control point for gene expression is the promoter, a sequence of DNA adjacent to the coding region of a gene where proteins bind and control the rate of transcription. The ability of these proteins to bind to the promoter is affected by the level of DNA methylation in the promoter. As we mentioned in [Key Concept 15.1](#), in certain regions of DNA many of the cytosine residues have methyl groups added at their 5 positions, forming 5-methylcytosine. If a gene promoter has a high degree of methylation, some proteins that promote transcription can't bind to it. Instead, other proteins bind to the methylated DNA and prevent expression of the gene. DNA methylation plays an important role in gene regulation and is a normal part of development. But the level of methylation can change over time and can vary among individuals, as was the case for the teenagers in Elbert and Meyer's study. Their finding is interesting because it shows a correlation between maternal stress in humans and DNA methylation in their offspring.

Such studies have spawned the new field of behavioral epigenetics. Epigenetics is the study of heritable changes in gene expression that do not involve changes in the DNA sequence. These changes may underlie behaviors in other animals as well. A fascinating example is the well-known behavior of a queen bee, who "lords it over" her genetically identical worker sisters. Genes in the brains of these two types of bees have very different patterns of expression, and these in turn are caused by epigenetic changes.

Can epigenetic changes be manipulated?

16.1 Prokaryotic Gene Expression Is Regulated in Operons

Prokaryotes conserve energy and resources by making certain proteins only when they are needed. The protein content of a bacterium can change rapidly when conditions warrant. Based on what you learned about gene expression in [Chapter 14](#), you might suggest several ways in which a prokaryotic cell could shut off the supply of an unneeded protein. The cell could:

- decrease the rate of transcription of mRNA for that protein;
- hydrolyze the mRNA after it is made, preventing translation;
- prevent translation of the mRNA at the ribosome;
- hydrolyze the protein after it is made; or
- inhibit the function of the protein.

Whichever mechanism is used, it must be both responsive to environmental signals and efficient. The earlier the cell intervenes in the process of protein synthesis, the less energy it wastes. Selective blocking of transcription is far more efficient than transcribing the gene, translating the message, and then degrading or inhibiting the protein. While all five mechanisms for regulating protein levels are found in nature, prokaryotes generally use the most efficient one: transcriptional regulation.

focus your learning

The *lac* operon is an example of an inducible operon regulated by a repressor protein.

Sigma factors provide another type of transcriptional regulation by directing RNA polymerases to specific promoters.

Gene expression begins at the ***promoter**, where RNA polymerase binds to initiate transcription. Note, however, that in a given cell at a given point in time, not all promoters are active. This observation suggests that gene transcription must be selective. The “decision” regarding which genes to activate involves two types of regulatory proteins that bind to DNA: repressor proteins and activator proteins. In both cases, these proteins bind to the promoter to regulate the gene (**Focus: Key Figure 16.1**):

focus: key figure

(A) Negative regulation

(B) Positive regulation

Figure 16.1 Positive and Negative Regulation Proteins regulate gene expression by binding to DNA and preventing or allowing RNA polymerase to bind DNA at the promoter region to control transcription of the gene.

Q: Could a gene be under both positive and negative regulation?

In **negative regulation**, binding of a repressor protein prevents transcription.

In **positive regulation**, an activator protein binds DNA to stimulate transcription.

negative regulation A type of gene regulation in which a gene is normally transcribed, and the binding of a repressor protein to the promoter prevents transcription. (Contrast with positive regulation.)

positive regulation A form of gene regulation in which a regulatory macromolecule is needed to turn on the transcription of a structural gene; in its absence, transcription will not occur. (Contrast with negative regulation.)

You will see examples of these mechanisms, or combinations of them, as we examine regulation in prokaryotes, eukaryotes, and viruses. We'll focus first on a regulatory system for the use of the sugar lactose.

Regulating gene transcription conserves energy

As a normal inhabitant of the human intestine, *E. coli* must be able to adjust to sudden changes in its chemical environment. Its host may present it with one foodstuff one hour (e.g., glucose in fruit) and another the next (e.g., lactose in milk). Such changes in nutrients present the bacterium with a metabolic challenge. Glucose is its preferred energy source, and is the easiest sugar to metabolize. Lactose is a β -galactoside—a disaccharide containing galactose β -linked to glucose (see [Key Concept 3.3](#)). Three proteins are involved in the initial uptake and metabolism of lactose by *E. coli*:

- . β -Galactoside permease is a carrier protein in the bacterial cell membrane that moves the sugar into the cell.
- . β -Galactosidase is an enzyme that hydrolyses lactose to glucose and galactose.
- . β -Galactoside transacetylase transfers acetyl groups from acetyl CoA to certain β -galactosides. Its role in the metabolism of lactose is not clear.

When *E. coli* grows and reproduces in a lab medium that contains glucose but no lactose or other β -galactosides, the levels of these three proteins are extremely low—the cell does not waste energy and materials making the unneeded enzymes. But if the environment changes such that lactose is the predominant sugar available and very little glucose is present, the bacterium promptly begins making all three enzymes after a short lag period. While few molecules of β -galactosidase are present in an *E. coli* cell in the presence of glucose, in the absence of glucose the addition of lactose can induce the synthesis of about 1,500 times more molecules of β -galactosidase per cell ([Figure 16.2A](#))!

(A) Lactose induces the synthesis of β -galactosidase

(B) Effect of inducer on mRNA level

Figure 16.2 An Inducer Stimulates the Expression of a Gene for an Enzyme (A)

When lactose is added to the growth medium for the bacterium *E. coli*, the synthesis of β -galactosidase begins only after an initial lag period. **(B)** There is a lag period because the mRNA for β -galactosidase has to be made before the protein can be made. The amount of mRNA decreases rapidly after the lactose is removed, indicating that transcription is no longer occurring. These changes in mRNA levels indicate that the mechanism of induction by lactose is transcriptional regulation.

What's behind this dramatic increase? An important clue comes from measuring the amount of mRNA for β -galactosidase. The mRNA level increases during the lag period after lactose is added to the medium, and this mRNA is translated into protein ([Figure 16.2B](#)). Moreover, the high mRNA level depends on the presence of lactose, because if the lactose is removed, the mRNA level goes down. *The response of the bacterial cell to lactose is clearly at the level of transcription.*

Compounds such as lactose that stimulate the synthesis of a protein are called **inducers**. The proteins that are produced are called **inducible proteins**, whereas proteins that are made all the time at a constant rate are called **constitutive proteins**. (Think of the constitution of a country, a document that does not change under normal circumstances.)

inducer (1) A compound that stimulates the synthesis of a protein. (2) In embryonic development, a substance that causes a group of target cells to differentiate in a particular way.

constitutive proteins Proteins that an organism produces all the time, and at a relatively constant rate.

We have now seen two basic ways of regulating the rate of a metabolic pathway. In [Key Concept 8.5](#) we described the allosteric regulation of enzyme activity, which allows the rapid fine-tuning of metabolism. Regulation of protein synthesis—that is, regulation of the concentration of enzymes—is slower but results in greater savings of energy and resources. Protein synthesis is a highly endergonic process, since assembling mRNA, charging tRNA, and moving the ribosomes along mRNA all require the hydrolysis of nucleoside triphosphates such

as ATP. [Figure 16.3](#) compares these two modes of regulation.

Figure 16.3 Two Ways to Regulate a Metabolic Pathway Feedback from the end product of a metabolic pathway can block enzyme activity (allosteric regulation), or it can stop the transcription of genes that code for the enzymes in the pathway (transcriptional regulation).

Operons are units of transcriptional regulation in prokaryotes

The genes in *E. coli* that encode the three enzymes for using lactose are structural genes; [structural genes](#) specify the primary structures (the amino acid sequences) of protein molecules that act as enzymes or cytoskeletal proteins. The three genes are adjacent to one another on the *E. coli* chromosome. This arrangement is no coincidence: the genes share a single promoter, and their DNA is transcribed into a single, continuous molecule of mRNA. Because this particular mRNA governs the synthesis of all three lactose-metabolizing enzymes, either all or none of these enzymes are made, depending on whether their common message—their mRNA—is present in the cell.

structural gene A gene that encodes the primary structure of a protein not involved in the regulation of gene expression.

A cluster of genes with a single promoter is called an [operon](#), and the operon that encodes the three lactose-metabolizing enzymes in *E. coli* is called the *lac* operon. The *lac* operon promoter can be very efficient (the maximum rate of mRNA synthesis can be high), but mRNA synthesis can be shut down when the enzymes are not needed. In addition to the promoter, an operon has other [regulatory sequences](#) that are not transcribed. A typical operon consists of a promoter, an operator, and two or more structural genes ([Figure 16.4](#)). The [operator](#) is a short stretch of DNA that lies between the promoter and the structural genes. It can bind very tightly with regulatory proteins that either activate or repress transcription.

operon A genetic unit of transcription, typically consisting of several structural genes that are transcribed together; the operon contains at least two control regions: the promoter and the operator.

regulatory sequence A DNA sequence to which the protein product of a regulatory gene binds.

operator The region of an operon that acts as the binding site for the repressor.

Figure 16.4 The *lac* Operon of *E. coli* The *lac* operon of *E. coli* is a segment of DNA that includes a promoter, an operator, and the three structural genes that code for lactose-metabolizing enzymes.

There are numerous mechanisms to control the transcription of operons; we will describe three examples:

- . An inducible operon regulated by a repressor protein
- . A repressible operon regulated by a repressor protein
- . An operon regulated by an activator protein

Operator–repressor interactions control transcription in the *lac* and *trp* operons

The *lac* operon contains a promoter, to which RNA polymerase binds to initiate transcription, and an operator, to which a **repressor** protein can bind. The gene that encodes this repressor is located near the *lac* operon on the *E. coli* chromosome. When the repressor is bound, transcription of the operon is blocked. This example of negative regulation was elegantly worked out by Nobel Prize winners François Jacob and Jacques Monod.

repressor A protein encoded by a regulatory gene that can bind to a promoter and prevent transcription of the associated gene. (Contrast with activator.)

The repressor protein has two binding sites: one for the operator and the other for the inducer. The environmental signal that induces the *lac* operon (for example, in the human digestive tract) is lactose, but the actual inducer is allolactose, a molecule that forms from lactose once it enters the cell. In the absence of the inducer, the repressor protein fits into the major groove of the operator DNA and recognizes and binds to a specific nucleotide base sequence. This prevents the binding of RNA polymerase to the promoter, and the operon is not transcribed (**Figure 16.5A**). When the inducer is present, it binds to the repressor and changes the shape of the repressor. This change in three-dimensional structure (conformation) prevents the repressor from binding to the operator. As a result, RNA polymerase can bind to the promoter and start transcribing the structural genes of the *lac* operon (**Figure 16.5B**).

(A) Lactose absent

(B) Lactose present

Figure 16.5 The *lac* Operon: An Inducible System (A) When lactose is absent, the synthesis of enzymes for its metabolism is inhibited. (B) Lactose (the inducer) leads to synthesis of the enzymes in the lactose-metabolizing pathway by binding to the repressor protein and preventing its binding to the operator.

Animation 16.1 The *lac* Operon www.Life11e.com/a16.1

You can see from this example that a key to transcriptional control of gene expression is the presence of regulatory sequences that do not code for proteins, but are binding sites for regulatory proteins and other proteins involved in transcription.

In contrast to the inducible system of the *lac* operon, other operons in *E. coli* are repressible; that is, they are repressed only under specific conditions. In such a system, the repressor is not normally bound to the operator. But if another molecule called a **co-repressor** binds to the repressor, the repressor changes shape and binds to the operator, thereby inhibiting transcription. An example is the *trp* operon, whose structural genes catalyze the synthesis of the amino acid tryptophan:

co-repressor In the regulation of bacterial operons, a molecule that binds to the repressor, causing it to change shape and bind to the operator, thereby inhibiting transcription.

When tryptophan is present in the cell in adequate concentrations, it is advantageous to stop making the enzymes for tryptophan synthesis. To do this, the cell uses a repressor that binds to an operator in the *trp* operon. But the repressor of the *trp* operon is not normally bound to the operator; it only binds when its shape is changed by binding to tryptophan, the co-repressor.

Let's pause to summarize the differences between these two types of operons:

In *inducible* systems, the substrate of a metabolic pathway (the inducer) interacts with a regulatory protein (the repressor), rendering the repressor incapable of binding to the operator and thus allowing transcription.

In *repressible* systems, the product of a metabolic pathway (the co-repressor) binds to a regulatory protein, which is then able to bind to the operator and block transcription.

Usually, inducible systems control ***catabolic pathways** (which are turned on only when the substrate is available), whereas repressible systems control anabolic pathways (which are turned on until the concentration of the product becomes excessive). In both systems, the regulatory protein is a repressor that functions by binding to the operator. Next we will consider an example of positive control involving an activator.

Animation 16.2 The *trp* Operon www.Life11e.com/a16.2

Protein synthesis can be controlled by increasing promoter efficiency

In negative control, transcription is *decreased* in the presence of a repressor protein. *E. coli* can also use positive control to *increase* transcription through the presence of an **activator** protein. For an example we return to the *lac* operon, where the relative levels of glucose and lactose determine the amount of transcription. We have seen that in the presence of lactose the *lac* repressor is unable to bind to the *lac* operator to repress transcription (see [Figure 16.5B](#)). But glucose is the preferred source of energy for the cell, so if glucose and lactose levels are both high, the *lac* operon is still not transcribed efficiently. This is because efficient transcription of the *lac* operon requires binding of an activator protein to its promoter.

activator A transcription factor that stimulates transcription when it binds to a gene's promoter. (Contrast with repressor.)

Low levels of glucose in the cell set off a signaling pathway that leads to increased levels of the second messenger cyclic AMP (cAMP) (see [Key Concept 7.3](#)). Cyclic AMP binds to an activator protein called cAMP receptor protein (CRP), producing a conformational change in CRP that allows it to bind to the *lac* promoter. CRP is an activator of transcription, because its

binding results in more efficient binding of RNA polymerase to the promoter, and thus increased transcription of the structural genes ([Figure 16.6](#)). In the presence of abundant glucose, cAMP levels are low, CRP does not bind to the promoter, and the efficiency of transcription of the *lac* operon is reduced. This is an example of [catabolite repression](#), a system of gene regulation in which the presence of the preferred energy source represses other catabolic pathways. The mechanisms controlling positive and negative regulation of the *lac* operon are summarized in [Table 16.1](#).

(A) Low glucose, lactose present

(B) High glucose, lactose present

Figure 16.6 Catabolite Repression Regulates the *lac* Operon (A) The promoter for the *lac* operon does not function efficiently in the absence of cAMP, as occurs when glucose levels are high. (B) High glucose levels thus repress the enzymes that metabolize lactose.

catabolite repression In the presence of abundant glucose, the diminished synthesis of catabolic enzymes for other energy sources.

table 16.1 Positive and Negative Regulation in the *lac* Operon

Glucose	cAMP levels	RNA polymerase binding to promoter	Lactose	<i>lac</i> Repressor	Transcription of <i>lac</i> genes?	Lactose used by cells?
Present	Low	Absent	Absent	Active and bound to operator	No	No
Present	Low	Present, not efficient	Present	Inactive and not bound to operator	Low level	No
Absent	High	Present, very efficient	Present	Inactive and not bound to operator	High level	Yes
Absent	High	Absent	Absent	Active and bound to operator	No	No

RNA polymerases can be directed to particular classes of promoters

Thus far we have described a promoter as a specific DNA sequence located upstream of a transcription initiation site. The promoter binds RNA polymerase so that the enzyme can then catalyze the synthesis of RNA from a gene-encoding region of DNA. The promoter also orients the polymerase so that it transcribes the correct one of the two DNA strands. Not all promoters are identical, but they all have similar sequences by which they are recognized by the RNA polymerase and other proteins. Prokaryotic promoters generally have two sites for these recognition sequences, which begin 10 and 35 base pairs upstream of the transcription start site (the -10 element and the -35 element). Different classes of promoters have different recognition sequences at these two sites. The largest class consists of promoters for “housekeeping genes,” which are all the genes that are normally expressed in actively growing cells. In these genes, the -10 element is 5′-TATAAT-3′, and the -35 element is 5′-TTGACAT-3′ (N stands for any nucleotide):

Other classes of genes have different recognition sequences at their -10 and -35 sites. Why do DNA recognition sequences differ in different classes of promoters? After all, aren't they all binding the same protein, RNA polymerase? The answer lies in the fact that these DNA sequences bind not just RNA polymerase but other proteins as well. And it is those other proteins that enhance RNA polymerase binding at certain promoters, thereby giving the system a degree of specificity.

Sigma factors are the proteins in prokaryotic cells that bind to RNA polymerase and direct it to specific classes of promoters. The RNA polymerase must be bound to a sigma factor before it can recognize a promoter and begin transcription. For example, the sigma-70 factor is active most of the time and binds to the recognition sequences of housekeeping genes; other sigma factors are activated only under specific conditions. When *E. coli* cells experience conditions such as DNA damage or osmotic stress, the sigma-38 factor is activated, and it directs RNA polymerase to the promoters of various genes that are expressed under stress conditions. *E. coli* has seven sigma factors; this number varies in other prokaryotes.

sigma factor In prokaryotes, a protein that binds to RNA polymerase, allowing the complex to bind to and stimulate the transcription of a specific class of genes (e.g., those involved in sporulation).

Regulation of proteins directing RNA polymerase to certain promoters is not unusual. In fact, you'll see in the next section that it is also common in eukaryotes.

16.1 recap

Gene expression in prokaryotes is most commonly regulated through control of transcription. An operon consists of a set of closely linked structural genes and a set of DNA sequences (promoter and operator) that control their transcription. Operons can be regulated by both negative and positive controls. Sigma factors control the expression of specific classes of prokaryotic genes that share recognition sequences in their promoters.

learning outcomes

You should be able to:

- Analyze conditions that affect expression of genes in the *lac* operon.
 - Describe the roles of various DNA sequences in the *lac* operon.
 - Explain how sigma factors and genetic sequences are involved in gene regulation in prokaryotes.
-
1. A prokaryotic cell can metabolize sugar "X," using the enzyme "Xase." When there is a low concentration of X in the environment, there is low activity of Xase in the cells; but when the X concentration is high, Xase is also high. What five mechanisms could the cell use to reduce the activity of Xase in the absence of X?
 2. Compare the molecular conditions at the *lac* operon promoter in the presence versus absence of lactose.
 3. How do sigma factors and recognition sequences act to affect the expression of classes of genes?
 4. The repressor protein that acts on the *lac* operon of *E. coli* is encoded by a regulatory gene. The repressor is made in small quantities and at a constant rate. Would you surmise that the promoter for this repressor protein is efficient or inefficient? Is synthesis of the repressor constitutive, or is it inducible and under environmental control?

Studies of bacteria have provided a basic understanding of mechanisms that regulate gene expression and of the roles of regulatory proteins in both positive and negative regulation. You'll see these same types of mechanisms again as we now turn to the transcriptional control of gene expression in eukaryotes.

***connect the concepts** A key DNA sequence involved in regulation is the promoter, where transcription begins and various regulatory proteins bind. Learn details about proteins at the promoter in [Key Concept 14.3](#).

***connect the concepts** As discussed in [Key Concept 8.1](#), there are two kinds of metabolism:

Catabolic pathways break down complex molecules into simpler ones, releasing energy formerly stored in the chemical bonds. Anabolic pathways link simple molecules to form more complex molecules, a process that requires an input of energy.

16.2 Eukaryotic Gene Expression Is Regulated by Transcription Factors

For cell function in single-celled eukaryotes as well as the normal development of a multicellular organism from fertilized egg to adult, certain proteins must be made at just the right times and in just the right cells; these proteins must not be made at other times in other cells. Here are two examples from humans:

- . In human pancreatic exocrine cells, the digestive enzyme procarboxypeptidase A makes up 7.6 percent of all the protein in the cell; in other cell types it is usually undetectable.
- . In human breast duct cells, alpha-lactalbumin, a protein in breast milk, is made only late in pregnancy and during lactation. Alpha-lactalbumin is not made in any other cell types.

Clearly the expression of eukaryotic genes is regulated.

focus your learning

The rate of transcription of a eukaryotic gene depends on the combination of transcription factors and other proteins binding to regulatory sequences associated with the gene.

DNA binding proteins have certain structural motifs in common that are important in their binding function.

Eukaryotic genes whose expression is coordinated share the same transcription factors.

As in prokaryotes, gene expression in eukaryotes can be regulated at several different points in the process of transcribing and translating the gene into a protein ([Figure 16.7](#)). In this section we will describe the mechanisms that result in the selective transcription of specific genes. The mechanisms for regulating gene expression in eukaryotes have similar themes as in those of prokaryotes. Both types of cells use DNA–protein interactions and negative and positive control. However, there are many differences, some of them dictated by the presence of a nucleus, which physically separates transcription and translation ([Table 16.2](#)).

Figure 16.7 Potential Points for the Regulation of Gene Expression Gene expression can be regulated before transcription (1), during transcription (2, 3), after transcription but before translation (4, 5), at translation (6), or after translation (7).

Q: In prokaryotes, transcription and translation are often coupled in time and space. But in eukaryotes they are separated. What are the advantages of the nucleus as a compartment?

 Activity 16.1 **Eukaryotic Gene Expression Control Points** www.Life11e.com/ac16.1

table 16.2 Transcription in Prokaryotes and Eukaryotes

	Prokaryotes	Eukaryotes
Locations of functionally related genes	Often clustered in operons	Often distant from one another with separate promoters

Promoters and other regulatory sequences	Few	Many
Initiation of transcription	Binding of RNA polymerase to promoter	Binding of many proteins, including RNA polymerase

General transcription factors act at eukaryotic promoters

As in prokaryotes, a promoter in a eukaryotic gene is a sequence of DNA near the 5' end of the coding region, where RNA polymerase binds and initiates transcription. Although eukaryotic promoters are more diverse than those of prokaryotes, many contain a nucleotide sequence similar to the -10 element in prokaryotic promoters. This element is usually located close to the transcription start site and is called the **TATA box** because it is rich in AT base pairs. The TATA box is the site where DNA begins to denature so that the template strand can be exposed. In addition to the TATA box, eukaryotic promoters typically include multiple regulatory sequences that are recognized and bound by **transcription factors**: regulatory proteins that help control transcription.

TATA box An eight-base-pair sequence, found about 25 base pairs before the starting point for transcription in many eukaryotic promoters, that binds a transcription factor and thus helps initiate transcription.

transcription factors Proteins that assemble on a eukaryotic chromosome, allowing RNA polymerase II to perform transcription.

Like the prokaryotic RNA polymerase, eukaryotic RNA polymerase II cannot simply bind to the promoter and initiate transcription. Rather, it does so only after various **general transcription factors** have assembled on the chromosome (**Figure 16.8**). General transcription factors bind to most promoters and are distinct from transcription factors that act only at certain promoters or classes of promoters. First, the protein complex called TFIID ("TF" stands for transcription factor) binds to the TATA box. Binding of TFIID changes both its own shape and that of the DNA, presenting a new surface that attracts the binding of other general transcription factors to form a transcription initiation complex. RNA polymerase II binds only after several other proteins

have bound to this complex.

general transcription factors In eukaryotes, transcription factors that bind to the promoters of most protein-coding genes and are required for their expression. Distinct from transcription factors that have specific regulatory effects only at certain promoters or classes of promoters.

Figure 16.8 The Initiation of Transcription in Eukaryotes Apart from TFIID, which

binds to the TATA box, each general transcription factor in this transcription complex has binding sites only for the other proteins in the complex, and does not bind directly to DNA. B, E, F, and H are general transcription factors.

Animation 16.3 Initiation of Transcription www.Life11e.com/a16.3

Each general transcription factor has a role in gene expression:

TFIIB binds both RNA polymerase and TFIID, and helps identify the transcription initiation site.

TFIIF prevents nonspecific binding of the complex to DNA and helps recruit RNA polymerase to the complex; it is similar in function to a bacterial sigma factor.

TFIIE binds to the promoter and stabilizes the denaturation of the DNA.

TFIIH opens up the DNA for transcription.

Some regulatory DNA sequences, such as the TATA box, are common to the promoters of many eukaryotic genes and are recognized by general transcription factors that are found in all the cells of an organism. Other regulatory sequences are present in only a few genes and are recognized by specific transcription factors. These factors may be found only in certain types of cells or at certain stages of the cell cycle, or they may be activated by signaling pathways in response to cellular or environmental signals (see [Chapter 7](#)).

Specific proteins can recognize and bind to DNA sequences and regulate transcription

Some regulatory DNA sequences are positive elements termed [enhancers](#): they bind transcription factors that either activate transcription or increase the rate of transcription. Other regulatory elements are [silencers](#): they bind factors that repress transcription. Most of the regulatory elements needed for correct expression of a gene are found within a few hundred base pairs of the transcription start site. For example, the mouse albumin gene promoter contains all the information needed for liver cell–specific expression within 170 base pairs upstream of the transcription start site. But some regulatory elements may be located thousands of base pairs away and they may affect the expression of several nearby genes. When transcription factors bind to these elements, they interact with the RNA polymerase complex, causing the DNA to bend ([Figure 16.9](#)).

enhancers Regulatory DNA sequences that bind transcription factors that either activate or increase the rate of transcription.

silencer A gene sequence binding transcription factors that repress transcription. (Contrast with promoter.)

Figure 16.9 Transcription Factors and Transcription Initiation The actions of many proteins determine whether and where RNA polymerase II will transcribe DNA.

The combination of transcription factors binding to a gene determines the rate of transcription. For example, the immature red blood cells in bone marrow make large amounts of (β -globin. At least 13 different transcription factors are involved in regulating transcription of the β -globin gene in these cells. Not all of these factors are present or active in other cells, such as the immature white blood cells produced by the same bone marrow. As a result, the β -globin gene is not transcribed in those cells. So although the same genes are present in all cells, the fate of the cell is determined by which of its genes are expressed. How do transcription factors recognize specific DNA sequences?

Specific protein–DNA interactions underlie binding

As we have seen, transcription factors with specific DNA-binding domains are involved in the activation and inactivation of specific genes. There are several common structural themes in the ***protein domains** that bind to DNA. These themes, or **structural motifs**, consist of different combinations of structural elements (protein conformations) and may include special components such as zinc. One of the common structural motifs is the helix-turn-helix, in which two a helices are connected via a non-helical turn. The interior-facing “recognition” helix interacts with the bases inside the DNA. The exterior-facing helix sits on the sugar–phosphate backbone, ensuring that the interior helix is presented to the bases in the correct configuration:

structural motif A three-dimensional structural element that is part of a larger molecule. For example, there are four common motifs in DNA-binding proteins: helix-turn-helix, zinc finger, leucine zipper, and helix-loop-helix.

Helix-turn-helix motif

Motif bound to DNA

How does a protein recognize a sequence in DNA? As you learned in [Key Concept 3.2](#), the complementary bases in DNA not only form hydrogen bonds with each other, but also can form additional hydrogen bonds with proteins, particularly at points exposed in the major and minor grooves. In this way, an intact DNA double helix can be recognized by a protein motif whose structure:

- fits into the major or minor groove;
- has amino acids that can project into the interior of the double helix; and
- has amino acids that can form hydrogen bonds with the interior bases.

Transcription factors underlie cell differentiation

During the development of a complex organism from fertilized egg to adult, cells become more and more differentiated (specialized). Differentiation is mediated in many cases by changes in gene expression, resulting from the activation (and inactivation) of various transcription factors. We will discuss this topic in more detail in [Chapter 19](#). For now, remember that all differentiated cells contain the entire genome, and that their specific characteristics arise from differential gene expression.

The expression of sets of genes can be coordinately regulated by transcription factors

How do eukaryotic cells coordinate the regulation of several genes whose transcription must be turned on at the same time? Prokaryotes solve this problem by arranging multiple genes in an operon that is controlled by a single promoter, and by using sigma factors to recognize particular classes of promoters. Most eukaryotic genes have their own separate promoters, and genes that are coordinately regulated may be far apart. In these cases, the expression of genes can be coordinated if they share regulatory sequences that bind the same transcription factors.

Shared regulatory sequences enable organisms to respond to stress— plants, for example, use shared regulatory sequences to respond to drought. Under conditions of drought stress, a plant must simultaneously synthesize several proteins whose genes are scattered throughout the genome. To coordinate expression of the stress response, each of the associated genes has a specific regulatory sequence near its promoter called the stress response element (SRE). A transcription factor binds to this element and stimulates mRNA synthesis ([Figure 16.10](#)). The stress response proteins not only help the plant conserve water, but also protect the plant against excess salt in the soil and freezing. This finding has considerable importance for agriculture because crops are often grown under less than optimal conditions or are affected by weather.

Figure 16.10 Coordinating Gene Expression A single environmental signal, such as drought stress, causes the synthesis of a transcription factor that acts on many genes.

16.2 recap

Eukaryotes can increase or decrease transcription in various ways to help regulate gene expression. A number of general transcription factors must bind to a eukaryotic promoter before RNA polymerase will bind to it and begin transcription. Other, specific transcription factors bind to regulatory DNA sequences and interact with the RNA polymerase complex to control differential gene expression.

learning outcomes

You should be able to:

- Explain the various ways that transcription factors regulate gene transcription.
 - Describe the elements present in transcription factors that allow them to recognize and bind specific regions of DNA.
 - Give an example of how eukaryotic genes widely separated by location are expressed in a coordinated fashion.
-

1. What are the ways whereby transcription factors regulate the rate of gene transcription?
2. How do transcription factors recognize specific DNA sequences?
3. How can more than one gene be regulated at the same time in a eukaryote?

We have seen how prokaryotes and eukaryotes regulate the transcription of their genes and operons. In the next section we will see how viruses can hijack prokaryotic and eukaryotic transcription mechanisms in order to complete their life cycles.

***connect the concepts** The structure and chemistry of DNA are key to its recognition by proteins. How the shapes and chemical structures of proteins allow them to bind noncovalently to other molecules is covered in [Key Concept 3.2](#).

16.3 Viruses Regulate Their Gene Expression during the Reproductive Cycle

“A virus is a piece of bad news wrapped in protein.” This quote from immunologist Sir Peter Medawar is certainly true for the cells that viruses infect. As we described in [Chapter 13](#), a bacterial virus (**bacteriophage**) injects its genetic material into a host bacterium and turns that cell into a virus factory (see [Figure 13.3](#)). Other viruses enter cells intact and then shed their coats and take over the cell’s replication machinery. Viral life cycles can be very efficient. An example is the poliovirus: a single poliovirus infecting a mammalian cell can produce more than 100,000 new virus particles!

bacteriophage (bak teer’ ee o fayj) [Gk. *bakterion*: little rod + *phagein*: to eat] Any of a group of viruses that infect bacteria. Also called phage.

focus your learning

A virus life cycle may be lytic or lysogenic.

Understanding the infection cycles of a virus makes it possible to design therapeutic agents to fight infections.

Viruses are small infectious agents that infect cellular organisms and that cannot reproduce outside their host cells. Most virus particles, called **virions**, consist of only two or three components: the genetic material made up of DNA or RNA, a protein coat that protects the genetic material, and in some cases, an envelope of lipids that surrounds the protein coat. As we will see in this section, viral genomes include sequences that encode regulatory proteins. These proteins “hijack” the host cells’ transcriptional machinery, allowing the viruses to complete their reproductive cycles.

virus Any of a group of ultramicroscopic particles constructed of nucleic acid and protein (and, sometimes, lipid) that require living cells in order to reproduce. Viruses evolved multiple times from different cellular species.

virion (veer’ e on) The virus particle, the minimum unit capable of infecting a cell.

Viruses undertake two kinds of reproductive cycles

After a viral genome enters a cell, typically the invader takes over the cells’ molecular genetic machinery. But in some cases, there is an alternate series of events, in which the viral genome becomes integrated into the host genome.

LYTIC CYCLE

The Hershey–Chase experiment (see [Figure 13.4](#)) involved a typical **lytic** viral reproductive cycle, so named because soon after infection, the host cell bursts (lyses), releasing progeny viruses. In this cycle, the viral genetic material takes over the host’s synthetic machinery for its own reproduction immediately after infection. In the case of some bacteriophages, the process

is extremely rapid—within 15 minutes, new phage particles appear in the bacterial cell. Ten minutes later, the “game is over,” and these particles are released from the lysed cell. What happened?

At the molecular level, the reproductive cycle of a typical lytic virus has two stages: early and late, as illustrated in [Figure 16.11](#). Follow along in the text and [Figure 16.11](#) and you’ll see examples of both positive and negative regulation, which stimulate and inhibit, respectively, gene expression:

(B)

Figure 16.11 The Lytic Cycle: A Strategy for Viral Reproduction (A) In a host cell infected with a virus, the viral genome uses its early genes to shut down host transcription while it replicates itself. Once the viral genome is replicated, its late genes produce capsid proteins that package the genome and other proteins that lyse the host cell. **(B)** Bacteriophages have attached to this *E. coli* cell, and the reproductive cycle is underway, producing new phage particles. The cell is viewed in transverse section.

The viral genome contains a promoter that binds host RNA polymerase. In the early stage (1–2 min after phage DNA entry), viral genes that lie adjacent to this promoter are transcribed (positive regulation).

These early genes often encode proteins that shut down host transcription (negative regulation) and stimulate viral genome replication and transcription of viral late genes (positive regulation). Three minutes after DNA entry, viral nuclease enzymes digest the host's chromosome, providing nucleotides for the synthesis of viral genomes.

In the late stage, viral late genes are transcribed (positive regulation); they encode the proteins that make up the **capsid** (the outer shell of the virus) and other protein components of the virus and enzymes that lyse the host cell to release the new virions. This begins 9 min after DNA entry and 6 min before the first new phage particles appear.

capsid The outer shell of a virus that encloses its nucleic acid.

The entire process— from binding and infection to release of new phage—takes about 30 min. During this period, the sequence of transcriptional events is carefully controlled to produce complete, infective virions.

LYSOGENIC CYCLE

Like all nucleic acid genomes, those of viruses can mutate and evolve by natural selection. Some viruses have evolved an advantageous process called **lysogeny** that postpones the lytic cycle. In lysogeny, the viral DNA becomes integrated into the host DNA and becomes a **prophage** (Figure 16.12). As the host cell divides, the viral DNA gets replicated along with that of the host. The prophage can remain inactive within the bacterial genome for thousands of generations, producing many copies of the original viral DNA.

lysogeny A form of viral replication in which the virus becomes incorporated into the host chromosome and remains inactive. Also called a lysogenic cycle. (Contrast with lytic cycle.)

prophage (pro' fayj) The noninfectious units that are linked with the chromosomes of the host bacteria and multiply with them but do not cause dissolution of the cell. Prophage can later enter into the lytic phase to complete the virus life cycle.

Figure 16.12 The Lytic and Lysogenic Cycles of Bacteriophages In the lytic cycle, infection of a bacterium by viral DNA leads directly to multiplication of the virus and lysis of the host cell. In the lysogenic cycle, an inactive prophage is integrated into the host DNA where it is replicated during the bacterial life cycle.

However, if the host cell is not growing well, the virus “cuts its losses.” It switches to a lytic cycle, in which the prophage excises itself from the host chromosome and reproduces. In other words, the virus is able to enhance its chances of multiplication and survival by inserting its DNA into the host chromosome, where it sits as a silent passenger until conditions are right for lysis.

Eukaryotic viruses can have complex life cycles

Eukaryotes are susceptible to infection by various kinds of viruses whose genomes may consist of RNA or DNA. A subgroup of RNA viruses are called retroviruses.

DNA viruses. Many viral particles contain double-stranded DNA. However, some contain single-stranded DNA, and a complementary strand is made after the viral genome enters the host cell. Like some bacteriophages, DNA viruses that infect eukaryotes are capable of undergoing both lytic and lysogenic life cycles. Examples include the herpes viruses and papillomaviruses (which cause warts).

RNA viruses. Some viral genomes are made up of RNA that is usually, but not always, single-stranded. The RNA is translated by the host’s machinery to produce viral proteins, some of which are involved in replication of the RNA genome. The influenza virus has an RNA genome.

Retroviruses. As we described in [Key Concept 14.2](#), a **retrovirus** is an RNA virus that carries a

gene for **reverse transcriptase**, a protein that synthesizes DNA from an RNA template. The ***retrovirus** uses this protein to make a DNA copy of its genome, which then becomes integrated into the host genome. The integrated DNA acts as a template for both mRNA and new viral genomes. HIV is a retrovirus that infects cells of the immune system and causes acquired immune deficiency syndrome (AIDS).

retrovirus An RNA virus that contains reverse transcriptase. Its RNA serves as a template for cDNA production, and the cDNA is integrated into a chromosome of the host cell.

reverse transcriptase An enzyme that catalyzes the production of DNA (cDNA), using RNA as a template; essential to the reproduction of retroviruses.

HIV gene regulation occurs at the level of transcription elongation

As we have discussed so far, many instances of gene regulation occur at the level of transcription *initiation*, involving both activator and repressor proteins that bind to the promoters of genes. However, studies of ***HIV** and other viruses have revealed that transcription can also be controlled at the *elongation* stage.

HIV is an **enveloped virus**; it is enclosed within a phospholipid membrane derived from its host cells (a specific type of immune system cell) (**Figure 16.13**). During infection, proteins in this membrane interact with proteins on the host cell surface, and the viral envelope fuses with the host cell membrane. After the virus enters the cell, its capsid is broken down. The viral reverse transcriptase then uses the virus's RNA template to produce a complementary DNA (cDNA) strand, while at the same time degrading the viral RNA. The enzyme then makes a complementary copy of the cDNA, and the resulting double-stranded DNA is inserted into the host's chromosome by an enzyme appropriately named integrase. The integrated DNA is referred to as the **provirus**. Both the reverse transcriptase and the integrase are carried inside the HIV virion, along with other proteins needed at the very early stages of infection.

enveloped virus A virus enclosed within a phospholipid membrane derived from its host cell.

provirus Double-stranded DNA made by a virus that is integrated into the host's chromosome and contains promoters that are recognized by the host cell's transcription apparatus.

Figure 16.13 The Reproductive Cycle of HIV This retrovirus enters a host cell via fusion of its envelope with the host's cell membrane. Reverse transcription of retroviral RNA then produces a DNA provirus—a molecule of complementary DNA that inserts itself into the host's genome.

Q: Looking at [Figures 16.12](#) and [16.13](#), can you classify HIV as a lytic or lysogenic virus?

The HIV provirus resides permanently in the host chromosome, and can remain in a latent (inactive) state for many years. During this time transcription of the viral DNA is initiated, but host cell proteins prevent the RNA from elongating, and transcription is terminated prematurely. Under some circumstances, such as when the host immune cell is activated, the level of transcription initiation increases and some viral RNA is made. One of these viral genes encodes a protein called tat (transactivator of transcription), which binds to a stem-and-loop structure at the 5' end of the viral RNA. As a result of tat binding, the production of full-length viral RNA is dramatically increased, and the rest of the viral reproductive cycle is able to proceed. It was only after the discovery of this mechanism in HIV and similar viruses that researchers found that many eukaryotic genes are regulated at the level of transcription elongation.

Almost every step in the reproductive cycle of HIV is, in principle, a potential target for drugs to treat AIDS. The classes of anti-HIV drugs currently in use include:

reverse transcriptase inhibitors that block viral DNA synthesis from RNA (at step 2 in [Figure 16.13](#));

integrase inhibitors that block the incorporation of viral DNA into the host chromosome (at step 3); and

protease inhibitors that block the posttranslational processing of viral proteins (at step 5).

Combinations of drugs from these classes have been spectacularly successful in treating HIV infection.

16.3 recap

A virus consists of nucleic acids, a few proteins, and in some cases, a lipid envelope. Viruses require host cells to reproduce. Viral life cycles can include lytic and lysogenic stages. Bacteriophages λ use both positive and negative regulators of transcription initiation. Studies of HIV revealed a new mechanism for gene regulation: the regulation of transcription elongation.

learning outcomes

You should be able to:

- Identify instances of positive and negative regulation of viral gene expression in prokaryotes.
- Predict how an anti-HIV drug would work at the molecular level.

1. Describe positive and negative regulation of gene expression in the bacteriophage λ and HIV life cycles.
2. If the function of the protease that cuts HIV protein was specifically blocked by a drug, what would be the effect on the HIV reproductive cycle?

So far we have discussed mechanisms that cells and viruses use to control gene transcription. These mechanisms usually involve the interaction of regulatory proteins with specific DNA sequences. However, there are other mechanisms for controlling gene expression that do not depend on specific DNA sequences. We will discuss these mechanisms in the next section.

***connect the concepts** Viral diversity is discussed in [Key Concept 25.4](#), which explains why the genomes of some viruses consist of single-stranded RNA and how RNA retroviruses reproduce themselves by reverse transcription.

***connect the concepts** Learn about HIV and its effects on the immune system in [Key Concept 41.6](#).

16.4 Epigenetic Changes Regulate Gene Expression

In the mid-twentieth century, the developmental biologist Conrad Hal Waddington coined the term “epigenetics” and defined it as “that branch of biology which studies the causal interactions between genes and their products which bring the phenotype into being.” Today [epigenetics](#) is defined more specifically, referring to the study of changes in gene expression that are prompted without changes in the DNA sequence.

epigenetics The scientific study of changes in the expression of a gene or set of genes that occur without change in the DNA sequence.

focus your learning

Methylation of cytosine bases in DNA can enhance the binding of repressor proteins to promoter regions, resulting in silencing of gene expression.

Acetylation and deacetylation of histone proteins alter the affinity of the histones for DNA, changing the accessibility of regions of the DNA to RNA polymerase.

Environmental factors can cause epigenetic changes.

Some heterochromatin such as the inactive X chromosome in female mammals results from extensive DNA methylation.

Epigenetic changes are reversible but sometimes are stable and heritable. You saw an example of this phenomenon in the opening story of this chapter, which described how genes inherited from mothers who had particularly stressful pregnancies were expressed at different levels than they were in children whose mothers had not suffered during pregnancy. In that example, stress—an environmental change—prompted a higher degree of DNA [methylation](#) in the promoter, reducing expression of a gene associated with behavior in teenagers. Here we examine more closely how epigenetic effects are caused either by DNA methylation or by alterations in chromosomal proteins.

methylation The addition of a methyl group (—CH_3) to a molecule.

DNA methylation occurs at the promoter and silences transcription

Depending on the organism, from 1 to 5 percent of cytosine residues in the organism’s DNA are chemically modified by the addition of a methyl group (—CH_3) to the 5-carbon, to form 5-methylcytosine ([Figure 16.14](#)). This covalent addition is catalyzed by the enzyme [DNA methyltransferase](#) and, in mammals, usually occurs in C residues that are adjacent to G residues. DNA regions rich in these doublets are called [CpG islands](#), and are especially abundant in promoters.

Figure 16.14 DNA Methylation: An Epigenetic Change The reversible formation of 5-methylcytosine in DNA can alter the rate of transcription.

Q: 5-methylcytosine is a mutational “hot spot” (see [Figure 15.5](#)). How might this relate to the importance of epigenetics in gene regulation?

DNA methyltransferase An enzyme that catalyzes the methylation of DNA.

CpG islands DNA regions rich in C residues adjacent to G residues. Especially abundant in

promoters, these regions are where methylation of cytosine usually occurs.

This covalent change in DNA is heritable: when DNA is replicated, a [maintenance methylase](#) catalyzes the formation of 5-methylcytosine in the new DNA strand. However, the pattern of cytosine methylation can also be altered, because methylation is reversible: a third enzyme, appropriately called [demethylase](#), catalyzes the removal of the methyl group from cytosine (see [Figure 16.14](#)).

maintenance methylase An enzyme that catalyzes the methylation of the new DNA strand when DNA is replicated.

demethylase An enzyme that catalyzes the removal of the methyl group from cytosine, reversing DNA methylation.

What is the effect of DNA methylation? During replication and transcription, 5-methylcytosine behaves just like plain cytosine: it base-pairs with guanine. But extra methyl groups in a promoter attract proteins that bind methylated DNA. These proteins are generally involved in the repression of gene transcription; thus heavily methylated genes tend to be inactive. *This form of genetic regulation is epigenetic because it affects gene expression patterns without altering the DNA sequence.*

DNA methylation is important in development from egg to embryo. For example, when a mammalian sperm enters an egg, many genes in first the male and then the female genome become de-methylated. Thus many genes that are usually inactive are expressed during early development. As the embryo develops and its cells become more specialized, genes whose products are not needed in particular cell types become methylated. These methylated genes are “silenced”; their transcription is repressed. However, unusual or abnormal events can sometimes turn silent genes back on.

For example, DNA methylation may play roles in the genesis of some cancers. In cancer cells, oncogenes get activated and promote cell division, and tumor suppressor genes (which normally inhibit cell division) are turned off (see [Chapter 11](#)). This misregulation can occur when the promoters of oncogenes become demethylated while those of tumor suppressor genes become methylated, as is the case in colorectal cancer (see [Figure 15.10](#)).

Histone protein modifications affect transcription

Another mechanism for epigenetic gene regulation is the alteration of chromatin structure, or chromatin remodeling. As we saw in [Chapter 11](#), DNA is packaged with histone proteins into nucleosomes (see [Figure 11.8](#)), which can make DNA physically inaccessible to RNA polymerase and the rest of the transcription apparatus. Each histone protein has a “tail” of approximately 20 amino acids at its N terminus that sticks out of the compact structure and contains certain positively charged amino acids (notably lysine). Ordinarily there is strong ionic attraction between the positively charged histone proteins and DNA, which is negatively charged because of its phosphate groups. However, enzymes called histone acetyltransferases can add acetyl groups to these positively charged amino acids, thus changing their charges:

Reducing the positive charges of the histone tails reduces the affinity of the histones for DNA, opening up the compact nucleosome ([Figure 16.15](#)). Additional chromatin remodeling proteins can bind to the loosened nucleosome-DNA complex, opening up the DNA for gene expression. Histone acetyltransferases can thus activate transcription.

Figure 16.15 Epigenetic Remodeling of Chromatin for Transcription Initiation of transcription requires that nucleosomes change their structure, becoming less compact. This chromatin remodeling makes DNA accessible to the transcription initiation complex (see [Figure 16.8](#)).

Another kind of chromatin remodeling protein, histone deacetylase, can remove the acetyl groups from histones and thereby repress transcription. Histone deacetylases are targets for drug development to treat some forms of cancer. As noted above, certain genes block cell division in normal specialized tissues. In some cancers these genes are less active than in normal cells, and the histones near them show excessive levels of deacetylation. Theoretically, a drug acting as a histone deacetylase inhibitor could tip the balance toward acetylation, and

this might activate genes that normally inhibit cell division.

Acetylation isn't the only type of histone modification that can affect gene activation and repression. For example, histone methylation (not to be confused with DNA methylation) is associated with gene inactivation, and histone phosphorylation also affects gene expression, the specific effects depending on which amino acids are modified. All of these effects are reversible, and so the activity of a eukaryotic gene may be determined by very complex patterns of histone modification.

Epigenetic changes can be induced by the environment

Female honey bees all have the same genetic makeup. When they are in the immature stage called a larva, however, one female in the hive eats a protein-rich substance called royal jelly that dramatically alters the expression of many genes. The queen grows much larger than her peers, stays in the hive, and is tended to by the other bees. Above all, the queen lives up to several years and is fertile, laying the eggs that will produce more bees. The multitudes of her female compatriot larvae express a different set of genes, becoming workers who build the honeycomb, forage for food, and tend to the queen for their short lives of a few weeks. All of these differences ultimately come from the environment, specifically the royal jelly diet. Recent investigations have shown that the differences in gene expression between these very different yet genetically identical bees are due to differences in DNA methylation (**Investigating Life: Gene Expression and Behavior**).

Although they are reversible, many epigenetic changes such as DNA methylation and histone modification can permanently alter gene expression patterns in a cell. In a germ line cell that forms gametes, epigenetic changes can be passed on to the next generation. But what determines these epigenetic changes? A clue comes from a recent study of monozygotic (identical) twins. Monozygotic twins come from a single fertilized egg that divides to produce two separate cells; each of these goes on to develop a separate individual.

Behavior

Gene Expression and

experiment

Original Paper: Kucharski, R., J. Maleszka, S. Foret and R. Maleszka. 2008. Nutritional control of reproductive status in honeybees via DNA methylation. *Science* 319: 1817–1830.

Most female honey bee larvae grow up to be workers; just one eats royal jelly and becomes the queen. To understand differences in gene expression in queen bees versus their sisters with identical genomes, Ryszard Maleszka and colleagues at Australian National University developed an experiment to test for possible epigenetic effects.

The experiment involved injecting female honey bee larvae with a substance that inhibits expression of the enzyme DNA cytosine-5-methyltransferase (DNMT)—the enzyme that catalyzes the formation of 5-methylcytosine from cytosine in DNA. In a technique called RNAi, the scientists injected female larvae with a small RNA complementary to the mRNA for DNMT to specifically block expression of the DNMT gene.

HYPOTHESIS DNA methylation underlies the developmental and behavioral differences between queen and worker honey bees.

METHOD

CONCLUSION Decreasing DNA methylation mimics the effects of royal jelly, causing larvae destined to become worker bees to instead become queens.

work with the data

QUESTIONS

- After injection with either an inhibitor of DNMT or a control, the level of DNMT mRNA was measured in the heads of the larvae and compared with the level of a control mRNA that is always expressed at a high level. The results are shown in **Table A**.

Table A

Time (h)	DNMT mRNA level compared to control (%)
23	105
48	41

- Why was mRNA measured in the heads of the larvae?
 - What can you conclude about the effectiveness of the inhibition of DNMT expression?
- The DNA of a gene that is normally expressed in the brain (head) of the larvae was sequenced and the percentage of 5-methylcytosine measured to determine the extent of cytosine methylation in CpG regions. **Table B** shows the results. What can you conclude about the effect of DNMT inhibition?

Table B

Condition	Percent 5-methylcytosine
Control	79
DNMT expression inhibited	63

- Larvae that had been injected with the inhibitor for DNMT gene expression or a control were allowed to develop into adults. The phenotypes of the adults were evaluated, and the data are shown in **Table C**. What do the data show about the effect of the inhibition of DNA methylation? Does the extent of DNA methylation strictly correlate with the extent of phenotypic change?

Table C

Condition	Number of workers	Number of queens
Control	238	73
Inhibited	74	188

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Monozygotic twins thus have identical genomes. But are they identical in their epigenomes? A comparison of DNA in hundreds of such twin pairs shows that in tissues of 3-year-olds, the DNA methylation patterns are virtually the same. But by age 50, by which time the twins have usually been living apart in different environments for decades, the patterns are quite different. This indicates that the *environment plays an important role in epigenetic modifications*, and thus in the regulation of genes that these modifications affect.

Media Clip 16.1 The Surprising Epigenetics of Identical Twins

www.Life11e.com/mc16.1

Global chromosome changes involve DNA methylation

Like single genes, large regions of chromosomes or even entire chromosomes can have distinct patterns of DNA methylation. Under a microscope, two kinds of chromatin can be distinguished in the stained interphase nucleus: **euchromatin** and **heterochromatin**. The euchromatin appears diffuse and stains lightly; it contains the DNA that is transcribed into mRNA.

Heterochromatin is condensed and stains darkly; any genes it contains are generally not transcribed.

euchromatin Diffuse, uncondensed chromatin. Contains active genes that will be transcribed into mRNA. (Contrast with heterochromatin.)

heterochromatin Densely packed, dark-staining chromatin; any genes it contains are usually not transcribed. (Contrast with euchromatin.)

Perhaps the most dramatic example of heterochromatin is the inactive X chromosome of mammals. A normal female mammal has two X chromosomes; a normal male has an X and a Y (see [Key Concept 12.4](#)). The X and Y chromosomes probably arose from a pair of autosomes (non-sex chromosomes) about 300 million years ago. Over time, mutations in the Y chromosome resulted in maleness-determining genes, and the Y chromosome gradually lost most of the genes it once shared with its X homolog. As a result, females and males differ greatly in the “dosage” of X-linked genes. Each female cell has two copies of each gene on the X chromosome and therefore has the potential to produce twice as much of each protein product. Nevertheless, for 75 percent of the genes on the X chromosome, transcription is generally the same in males and in females. How does this happen?

During early embryonic development, one of the X chromosomes in each cell of a female is largely inactivated with regard to transcription. The same X chromosome remains inactive in all of that cell's descendants. In a given embryonic cell, the “choice” of which X in the pair to inactivate is random. Recall that one X in a female comes from her father and one from her mother. Thus in one embryonic cell the paternal X might be the one remaining transcriptionally active, but in a neighboring cell the maternal X might be active.

The inactivated X chromosome is identifiable within the nucleus because it is very compact, even during interphase. Typically, a nuclear structure called a Barr body (after its discoverer, Murray Barr) can be seen in human female cells under the light microscope ([Figure 16.16A](#)). This clump of heterochromatin, which is not present in normal males, is the inactivated X chromosome, and it consists of heavily methylated DNA. A female with the normal two X chromosomes will have one Barr body, whereas a rare female with three Xs will have two, and an XXXX female will have three. Males that are XXY will have one. These observations suggest that the interphase cells of each person, male or female, have a single active X chromosome, and thus a constant dosage of expressed X chromosome genes.

Figure 16.16 X Chromosome Inactivation (A) A Barr body and an active X chromosome in the nucleus of a human female cell. The X chromosomes are stained with a yellow-green fluorescent dye; the other chromosomes are stained with a red fluorescent dye. (B) A model for X chromosome inactivation.

Condensation of the inactive X chromosome makes its DNA sequences physically unavailable to the transcriptional machinery. Most of the genes of the inactive X are heavily methylated. However, one gene, *Xist* (for X inactivation-specific transcript), is only lightly methylated and is transcriptionally active. On the active X chromosome, *Xist* is heavily methylated and not

transcribed. The RNA transcribed from *Xist* binds to the X chromosome from which it is transcribed, and this binding leads to a spreading of inactivation along the chromosome. The *Xist* RNA transcript is an example of [interference RNA](#) ([Figure 16.16B](#)).

interference RNA (RNAi) See **RNA** interference.

16.4 recap

Epigenetics describes stable changes in gene expression that do not involve changes in DNA sequences. These changes involve modifications of DNA (cytosine methylation) or of histone proteins bound to DNA. Epigenetic changes can be affected by the environment. Large stretches of DNA can be epigenetically modified, leading to inactivation of many genes.

learning outcomes

You should be able to:

- Describe the role of methylation in gene expression.
- Explain how acetylation of proteins changes the structure of chromatin and affects the rate of transcription.
- Cite evidence supporting the claim that environmental effects have a strong role in epigenetic changes.
- Describe how and where X chromosome inactivation occurs, and explain why it is believed to occur.

1. How do histone modifications affect transcription?
2. What is the evidence that epigenetic modifications affect behavior?
3. How does X chromosome inactivation occur, and why is it believed to occur?
4. In colorectal cancer, certain tumor suppressor genes are not active, and this results in uncontrolled cell division. Two possible explanations for the inactive genes are (a) mutations in the coding regions, resulting in inactive proteins, and (b) epigenetic silencing at the promoters of the genes, resulting in reduced transcription. How would you investigate these two possibilities?

Gene expression involves transcription and then translation. So far we have described how gene expression is regulated at the transcriptional level. But as [Figure 16.7](#) shows, there are many points at which regulation can occur after the initial gene transcript is made.

16.5 Eukaryotic Gene Expression Can Be Regulated after Transcription

Eukaryotic gene expression can be regulated both in the nucleus prior to mRNA export, and after the mRNA leaves the nucleus. This can happen in several ways.

focus your learning

Alternative splicing can give rise to multiple mRNA molecules from a single primary mRNA transcript.

MicroRNAs (miRNAs) are short single-stranded RNA molecules complementary to mRNAs that bind to and inhibit mRNAs from being translated.

Small interfering RNAs (siRNAs) perform a similar role in the cell as miRNAs but have a viral origin.

Single-stranded RNA can form secondary structures that inhibit its translation.

The cell tags proteins to be degraded with ubiquitin, which leads to its binding to a proteasome, where degradation occurs.

RNA splicing can result in different mRNAs being made from the same gene

Most primary mRNA transcripts contain several introns (see [Figure 14.7](#)). Before the RNA is exported from the nucleus, a splicing mechanism recognizes the boundaries between exons and introns and converts pre-mRNA, which has the introns, into mature mRNA, which does not:

For many genes, [alternative splicing](#) can occur, whereby some exons are spliced out along with the introns ([Figure 16.17](#)). This mechanism generates a family of different proteins, with different functions, from a single gene. Recent surveys show that about half of all human genes are alternatively spliced. Alternative splicing may be a key to the differences in levels of complexity among organisms. For example, although humans and chimpanzees have similar-sized genomes, there is more alternative splicing in the human brain than in the chimpanzee brain.

alternative splicing A process for generating different mature mRNAs from a single gene by splicing together different sets of exons during RNA processing.

Figure 16.17 Alternative Splicing Results in Different Mature mRNAs and Proteins Pre-mRNA can be spliced differently in different tissues, resulting in different proteins.

Q: A protein-encoding gene in a eukaryote has four introns. How many different proteins could be made by alternative splicing of the pre-mRNA from this gene?

Alternative RNA splicing is controlled both by regulatory elements in the RNA sequence that bind specific proteins (similar to regulatory sequences in DNA) and by secondary RNA structures that form by hybridization between nucleotides in the single-stranded RNA molecule.

Small RNAs are important regulators of gene expression

As you'll see in [Chapter 17](#), less than 5 percent of the genome in most plants and animals codes for proteins. Some of the genome encodes ribosomal RNA and transfer RNAs, but until recently biologists thought that the rest of the genome was not transcribed; some even called it "junk." Recent investigations, however, have shown that some of these noncoding regions are transcribed. The RNAs produced from these regions are often very small and therefore difficult to detect. In both prokaryotes and eukaryotes, these tiny RNA molecules are called [microRNA \(miRNA\)](#).

microRNA (miRNA) A small, noncoding RNA molecule, typically about 21 bases long, that binds to mRNA to inhibit its translation.

There are as many as 5,000 miRNAs, with about 1,000 of them encoded in the human genome. Each miRNA is about 22 bases long and usually has dozens of mRNA targets because the base pairing between the miRNA and the target mRNA doesn't have to be perfect. MicroRNAs are transcribed as longer precursors that fold into double-stranded RNA molecules and are then processed through a series of steps into single-stranded miRNAs. A protein complex guides the miRNA to its target mRNA, where translation is inhibited ([Figure 16.18A](#)). The remarkable conservation of the miRNA gene-silencing mechanism indicates that it is evolutionarily ancient and biologically important.

Figure 16.18 mRNA Inhibition by RNAs MicroRNAs and small interfering RNAs can inhibit translation by binding to target mRNAs.

In addition to miRNAs, there is a similarly acting class of molecules called **small interfering RNAs (siRNAs)**. These often arise from viral infections, when two complementary strands of a viral genome are transcribed. Large double-stranded RNAs are formed, and as with miRNAs, these are converted into shorter single-stranded sequences; these bind to the target RNA and cause its degradation (**Figure 16.18B**). Small interfering RNAs are also derived from transposon sequences, which are widespread in eukaryotic genomes (see [Key Concept 15.1](#)). Therefore it

is likely that gene silencing involving siRNAs evolved as a defense mechanism to prevent the translation of viral and transposon sequences. MicroRNAs and siRNAs are similar molecules that are processed by the same cellular enzymes. A major difference between them is that:

small interfering RNAs See siRNAs.

siRNAs (small interfering RNAs) Short, double-stranded RNA molecules used in RNA interference.

miRNAs are synthesized from DNA sequences separate from their target, whereas siRNAs are targeted to their sequence of origin.

Translation of mRNA can be regulated by proteins

From what we have described in this chapter so far, you may get the impression that in eukaryotes all regulation of gene expression is at the level of transcription. But is the amount of a protein in a cell really determined only by the amount of its mRNA? The answer is no. For example, a survey of genes and their expression in yeast cells showed that for about one-third of the genes, there was a clear correlation between mRNA and protein: more of one led to more of the other. But for two-thirds of the genes, there was no apparent relationship between the two: sometimes there was lots of mRNA and little or no protein, or lots of protein and little mRNA. The concentrations of these proteins must therefore have been determined by factors acting after the mRNA was made. Cells have two major ways to control the amount of a protein after transcription:

- . They can regulate translation of the protein's mRNA.
- . They can regulate how long a newly synthesized protein persists in the cell (protein longevity).

REGULATION OF TRANSLATION

There are a variety of ways in which the translation of mRNA can be regulated. One way, as we saw in the previous section, is to inhibit translation with siRNAs and miRNAs. A second way involves modification of the guanosine triphosphate cap on the 5' end of the mRNA (see [Key Concept 14.4](#)). An mRNA that is capped with an unmodified GTP molecule is not translated. For example, stored mRNAs in the egg cells of the tobacco hornworm moth are capped with unmodified GTP molecules and are not translated. After the egg is fertilized, however, the caps are modified, allowing the mRNA to be translated to produce the proteins needed for early embryonic development.

In another system, repressor proteins directly block translation. For example, in mammalian cells the protein ferritin binds free iron ions (Fe^{2+}). When iron is present in excess, ferritin synthesis rises dramatically, but the amount of ferritin mRNA remains constant, indicating that the increase in ferritin synthesis is due to an increased rate of mRNA translation. Indeed, when the iron level in the cell is low, a translational repressor protein binds to the 5' noncoding region of ferritin mRNA and prevents its translation by blocking its attachment to a ribosome. When the iron level rises, some of the excess Fe^{2+} ions bind to the repressor and alter its three-dimensional structure, causing the repressor to detach from the mRNA and allowing translation to proceed ([Figure 16.19](#)). The binding site for the translational repressor on mRNA is a stem-and-loop region with sufficient three-dimensional structure for recognition by a protein or small molecule.

Figure 16.19 A Translational Repressor Can Repress Translation Binding of a protein to a target mRNA can inhibit its translation.

REGULATION OF PROTEIN LONGEVITY

The protein content of a cell at any given time is a function of both protein synthesis and protein degradation. Certain proteins can be targeted for destruction in a chain of events that begins when an enzyme attaches a 76-amino acid protein called **ubiquitin** (so named because it is ubiquitous, or widespread) to a lysine residue of the protein to be destroyed. Other ubiquitins then attach to the primary one, forming a polyubiquitin chain. The protein–polyubiquitin complex then binds to a huge protein complex called a **proteasome** (from *protease* + *soma*, “body”) (**Figure 16.20**). Upon entering the proteasome, the polyubiquitin is removed and ATP energy is used to unfold the target protein. Three different proteases then digest the protein into small peptides and amino acids.

ubiquitin A small protein that is covalently linked to other cellular proteins identified for breakdown by the proteasome.

proteasome In the eukaryotic cytoplasm, a huge protein structure that binds to and digests cellular proteins that have been tagged by ubiquitin.

Figure 16.20 A Proteasome Breaks Down Proteins Proteins targeted for degradation are bound to ubiquitin, which then binds the targeted protein to a proteasome. The proteasome is a complex structure where proteins are digested by several powerful proteases.

You may recall from [Key Concept 11.2](#) that cyclins are proteins that regulate the activities of key enzymes at specific points in the cell cycle. Cyclins must be broken down at just the right time, and this is done by attaching ubiquitin to them and degrading them in the proteasomes. Viruses can hijack this system. For example, some strains of the human papillomavirus (HPV) add ubiquitin to the p53 and retinoblastoma proteins, targeting them for proteasomal degradation. These proteins normally inhibit the cell cycle, so the result of this HPV activity is unregulated cell division (cancer).

16.5 recap

One of the most important means of posttranscriptional regulation is alternative RNA splicing, which allows more than one protein to be made from a single gene. The stability of mRNA in the cytoplasm can also be regulated. MicroRNAs, siRNAs, mRNA modifications, and translational repressors can prevent mRNA translation. Proteins in the cell can be targeted for breakdown by ubiquitin and then hydrolyzed in proteasomes.

learning outcomes

You should be able to:

- Explain the differences in the number of protein-coding genes and the number of proteins in a cell.
- Explain how miRNAs regulate translation of mRNA.
- Compare and contrast miRNAs and siRNAs.
- Suggest a way that the structure of an mRNA molecule could affect its translation.
- Describe the function of the proteasome in a cell.

1. How do miRNAs and siRNAs regulate gene expression?
2. How does the three-dimensional structure of mRNA contribute to the regulation of its expression?
3. What is the role of the proteasome?
4. Before the human genome was sequenced, most scientists thought it contained 80,000 to 150,000 protein-coding genes. The actual sequence revealed only about 21,000. How can mRNA explain this discrepancy?
5. Pharmaceutical companies are interested in developing miRNA drugs. How might they work in cancer? (Hint: See [Figure 11.23](#), about oncogene and tumor suppressor proteins.)

investigatinglife

Can epigenetic changes be manipulated?

In the opening story, you saw how epigenetic changes in cytosine methylation of a gene encoding a receptor resulted in behavioral changes in people's response to stress. In Investigating Life: Gene Expression and Behavior, you learned that epigenetic changes underlie the differences between worker and queen bees. Both examples involve changes in DNA that were triggered by the environment and resulted in altered gene expression.

As in bees, nutrients in the diets of mammals (including humans), such as folic acid and SAM-e (S-adenosyl methionine), contain methyl groups that can participate in reactions that modify DNA. Experiments with mice have shown that feeding young animals a diet enriched with these nutrients causes changes in epigenetic patterns and gene expression that remain throughout life. A new field with the name nutriepigenomics (could you have guessed name?) has developed to investigate the possibility of altering gene expression in mammals by diet.

Future directions

In addition to the altering of DNA methylation by diet, specific drugs have been developed that target the enzymes involved in this phenomenon. In cancer, gene expression can be altered in many ways, such as by mutation (as you saw in [Chapter 11](#)). Cancer cells can alter gene expression through epigenetic mechanisms as well. For example, in some colon cancers, the expression of an important tumor suppressor gene involved in DNA repair is silenced by extensive DNA methylation at the promoter, resulting in uncontrolled cell division. The nucleotide analog 5'-azacytidine blocks DNA methyltransferase and can be employed to combat some cancers, by reducing DNA methylation and halting uncontrolled cell division. Other drugs are being used to block histone modifications that in the tumor cell result in gene expression changes.

▶ 16.1 Prokaryotic Gene Expression Is Regulated in Operons

- Some proteins are synthesized only when they are needed. Proteins that are made only in the presence of a particular compound—an **inducer**—are called **inducible proteins**. Proteins that are made at a constant rate regardless of conditions are called **constitutive proteins**. **Review Focus: Key Figure 16.1, Figure 16.2**

inducer (1) A compound that stimulates the synthesis of a protein. (2) In embryonic development, a substance that causes a group of target cells to differentiate in a particular way.

constitutive proteins Proteins that an organism produces all the time, and at a relatively constant rate.

- An **operon** consists of a promoter, an **operator**, and two or more **structural genes**. Promoters and operators do not code for proteins, but serve as binding sites for regulatory proteins. **Review Figure 16.4**

operon A genetic unit of transcription, typically consisting of several structural genes that are transcribed together; the operon contains at least two control regions: the promoter and the operator.

operator The region of an operon that acts as the binding site for the repressor.

structural gene A gene that encodes the primary structure of a protein not involved in the regulation of gene expression.

- Regulatory genes code for regulatory proteins, such as **repressors**. When a repressor binds to an operator, transcription of the structural gene is inhibited. **Review Figure 16.5, Animations 16.1, 16.2**

repressor A protein encoded by a regulatory gene that can bind to a promoter and prevent transcription of the associated gene. (Contrast with activator.)

- The *lac* operon is an example of an inducible system, in which the presence of an inducer (lactose) keeps the repressor from binding the operator, allowing the transcription of structural genes for lactose metabolism.
- Transcription can be enhanced by the binding of an **activator** protein to the promoter. **Review Figure 16.6**

activator A transcription factor that stimulates transcription when it binds to a gene's promoter. (Contrast with repressor.)

- Catabolite repression** is the inhibition of a catabolic pathway for one energy source by a different, preferred energy source.

catabolite repression In the presence of abundant glucose, the diminished synthesis of catabolic enzymes for other energy sources.

▶ 16.2 Eukaryotic Gene Expression Is Regulated by Transcription Factors

- Eukaryotic gene expression can be regulated before, during, and after transcription. [Review Figure 16.7](#), [Activity 16.1](#)
- [Transcription factors](#) and other proteins bind to DNA and affect the rate of initiation of transcription at the promoter. [Review Figures 16.8](#), [16.9](#), [Animation 16.3](#)

transcription factors Proteins that assemble on a eukaryotic chromosome, allowing RNA polymerase II to perform transcription.

- The interactions of these proteins with DNA are highly specific and depend on protein domains and DNA sequences.
- Genes at distant locations from one another can be coordinately regulated by transcription factors and promoter elements. [Review Figure 16.10](#)

▶ 16.3 Viruses Regulate Their Gene Expression during the Reproductive Cycle

- [Viruses](#) are not cells, and rely on host cells to reproduce.

virus Any of a group of ultramicroscopic particles constructed of nucleic acid and protein (and, sometimes, lipid) that require living cells in order to reproduce. Viruses evolved multiple times from different cellular species.

- The basic unit of a virus is a [virion](#), which consists of a nucleic acid genome (DNA or RNA); a protein coat, called a [capsid](#); and in some cases, an envelope of lipids that surrounds the capsid.

virion (veer' e on) The virus particle, the minimum unit capable of infecting a cell.

capsid The outer shell of a virus that encloses its nucleic acid.

- [Bacteriophages](#) are viruses that infect bacteria.

bacteriophage (bak teer' ee o fayj) [Gk. *bakterion*: little rod + *phagein*: to eat] Any of a group of viruses that infect bacteria. Also called phage.

- Viruses undergo a **lytic** cycle, which causes the host cell to burst, releasing new virions.
- Some viruses have promoters that bind host RNA polymerase, which they use to transcribe their own genes and proteins. [Review Figure 16.11](#)
- Some viruses can also undergo [lysogeny](#), in which a molecule of their DNA, called a [prophage](#), is inserted into the host chromosome, where it replicates for generations. [Review Figure 16.12](#)

lysogeny A form of viral replication in which the virus becomes incorporated into the host

chromosome and remains inactive. Also called a lysogenic cycle. (Contrast with lytic cycle.)

prophage (pro' fayj) The noninfectious units that are linked with the chromosomes of the host bacteria and multiply with them but do not cause dissolution of the cell. Prophage can later enter into the lytic phase to complete the virus life cycle.

- A **retrovirus** uses **reverse transcriptase** to generate a cDNA **provirus** from its RNA genome. The provirus is incorporated into the host's DNA and can be activated to produce new virions. **Review Figure 16.13**

retrovirus An RNA virus that contains reverse transcriptase. Its RNA serves as a template for cDNA production, and the cDNA is integrated into a chromosome of the host cell.

reverse transcriptase An enzyme that catalyzes the production of DNA (cDNA), using RNA as a template; essential to the reproduction of retroviruses.

provirus Double-stranded DNA made by a virus that is integrated into the host's chromosome and contains promoters that are recognized by the host cell's transcription apparatus.

▶ 16.4 Epigenetic Changes Regulate Gene Expression

- **Epigenetics** refers to changes in gene expression that do not involve changes in DNA sequences.

epigenetics The scientific study of changes in the expression of a gene or set of genes that occur without change in the DNA sequence.

- **Methylation** of cytosine residues generally inhibits transcription. **Review Figure 16.14**

methylation The addition of a methyl group ($-\text{CH}_3$) to a molecule.

- Modifications of histone proteins in nucleosomes make transcription either easier or more difficult. **Review Figure 16.15**
- Changes in the environment, such as drought stress, can prompt epigenetic changes to occur. **Review Investigating Life: Gene Expression and Behavior**

▶ 16.5 Eukaryotic Gene Expression Can Be Regulated after Transcription

- **Alternative splicing** of pre-mRNA can produce different proteins. **Review Figure 16.17**

alternative splicing A process for generating different mature mRNAs from a single gene by splicing together different sets of exons during RNA processing.

- Small RNAs (**microRNAs** and **small interfering RNAs**) do not code for proteins but regulate the translation and longevity of mRNA. **Review Figure 16.18**

microRNA (miRNA) A small, noncoding RNA molecule, typically about 21 bases long, that binds to mRNA to inhibit its translation.

small interfering RNAs See siRNAs.

- The translation of mRNA to proteins can be regulated by translational repressors.

- A [proteasome](#) can break down proteins, thus affecting protein longevity. **Review** [Figure 16.20](#)

proteasome In the eukaryotic cytoplasm, a huge protein structure that binds to and digests cellular proteins that have been tagged by ubiquitin.

See [Activity 16.2](#) for a concept review of this chapter.

Review

- 6.4 Methylation of cytosine bases in DNA can enhance the binding of repressor proteins to promoter regions, resulting in silencing of gene expression.
- 6.4 Acetylation and deacetylation of histone proteins alter the affinity of the histones for DNA, changing the accessibility of regions of the DNA to RNA polymerase.

Original Paper: Bovenzi, V. and R. L. Momparler, 2001. Antineoplastic action of 5-aza-2'deoxyctidine and histone deacetylase inhibitor and their effect on the expression of the retinoic acid receptor β and estrogen receptor α genes in breast carcinoma cells. *Cancer Chemotherapy and Pharmacology* 48: 71–76.

Cancer cells do not stop dividing. In some types of cancer, this happens because oncogenes that signal the go-ahead at cell cycle checkpoints are continually expressed, while tumor suppressor genes that inhibit progression through checkpoints are silenced. So when a group of researchers observed a pattern of gene silencing in breast cancer cells, they wondered if they could intervene. If the genes had been silenced as the result of DNA methylation or histone deacetylation, perhaps the researchers could induce expression of the genes by reversing DNA methylation and/or histone deacetylation.

Recall that DNA methyltransferase adds methyl groups onto cytosines in DNA, while a demethylase catalyzes the reverse reaction. Methylation of promoter regions in DNA inhibits gene expression; de-methylation activates gene expression.

Recall, too, that chromatin can undergo remodeling as histones undergo reversible acetylation and deacetylation of lysine residues. Acetylation of histones activates gene expression; deacetylation inhibits gene expression.

With this in mind, the researchers decided to treat the breast cancer cells with two different inhibitors: AZA, a compound that inhibits DNA methyltransferase; and TSA, a compound that inhibits histone deacetylase. The researchers looked at the effects of both inhibitors, first separately and then together (see graph at right), on the growth of the cancer cells.

In another experiment, the researchers measured the expression of two genes that have been shown to be silenced in these cancer cells. At the beginning of the experiment, cancer cells were either incubated with each inhibitor separately or with the two inhibitors combined. The researchers then isolated RNA from the cells and used the polymerase chain reaction (PCR) to

amplify mRNA that had been expressed from the genes of interest. They compared the quantities of the amplified products, which were proportional to the quantities of the original mRNA transcripts that had been expressed in the cells during their treatment. The results are shown in the table below.

Untreated control of mRNA transcript of:	Treatment		
	AZA	TSA	AZA + TSA
Gene 1	7	23	25
Gene 2	<1	<1	11

Questions

1. Analyze the results shown for the single drugs. What do the data suggest about the roles of DNA methylation and histone deacetylation in gene expression in this cell line?
2. Analyze and explain the results shown for both drugs together as they compare with the results for the single drugs. What do the results suggest about the combined effect of DNA methylation and histone acetylation on gene expression in these cells?
3. Analyze the gene expression data in the table. What do these data suggest about the mechanism of silencing of each gene?

The Dog Genome Project

Canis lupus familiaris, the dog, was domesticated by humans thousands of years ago. While there are many kinds of wolves, they all look about the same. Not so with “man’s best friend.” The American Kennel Club recognizes about 155 different breeds, which not only look different but also vary greatly in size. For example, an adult Chihuahua weighs just 1.5 kg, whereas a Scottish deerhound weighs 70 kg. No other mammal shows such large phenotypic variation. Also, there are hundreds of genetic diseases in dogs, many of which have counterparts in humans. To study the genes behind the phenotypic variation, and to elucidate the relationships between genes and diseases, the Dog Genome Project was started in the late 1990s.

Two dogs—a boxer and a poodle—were the first to have their entire genomes sequenced. The dog genome contains 2.8 billion base pairs of DNA in 39 pairs of chromosomes. There are 19,000 protein-coding genes, most with close counterparts in other mammals, including humans. Given the whole genome sequence, researchers began to map genetic markers—specific nucleotides or short sequences of DNA— at particular locations on the genome that differ among individual dogs or breeds.

Genetic markers can map the locations of (and thus identify) genes that control particular traits. For example, Dr. Elaine Ostrander and her colleagues at the National Institutes of Health studied Portuguese water dogs to identify genes that control size. Samples of cells for DNA isolation were obtained by sweeping a cotton swab over the inside of the cheek. It turned out that the gene for insulin-like growth factor 1 (IGF-1) is important in determining size: large breeds have an allele that codes for an active IGF-1, and small breeds have a different allele that codes for a less active IGF-1.

Inevitably, some scientists set up companies to test dogs for genetic variations, using DNA supplied by people anxious to validate the “purebred” status of their dogs. Not to be outdone, cat fanciers have sequenced the genomes of domestic and wild cats. Comparisons of these animal genomes help establish the evolutionary history of mammalian lineages as well as identify the genes responsible for diseases and traits seen in various mammalian species.

What have we learned from sequencing animal genomes?

17.1 Genomes Can Be Sequenced Rapidly

Genome sequencing involves determining the nucleotide base sequence of the entire genome of an organism. For a prokaryotic organism with a single chromosome, the genome sequence is one continuous series of base pairs (bp). In the case of a diploid, sexually reproducing species with multiple autosomes and a pair of sex chromosomes (see [Key Concept 12.4](#)), the “sequenced genome” usually means the sequence of all the bases in one set of autosomes and in each of the two sex chromosomes.

genome sequencing Determination of the nucleotide base sequence of the entire genome of an organism.

focus your learning

Genomes are sequenced in short fragments that are ordered through overlaps.

Functional genomics uses sequence information to identify the functions of various parts of the genome.

Comparative genomics compares sequences in genomes from different organisms.

With advances in the technology for DNA sequencing, there has been an explosion of genetic information that scientists can use in a variety of ways:

The genomes of different species can be compared to find out how they differ at the DNA level, and this information can be used to trace evolutionary relationships.

The sequences of individuals within a species can be compared to identify mutations that affect particular phenotypes.

Sequence information can be used to identify genes for particular traits, such as genes associated with diseases.

The base sequence of a short DNA fragment can be determined quickly

The notion of sequencing the entire genome of a complex organism was not contemplated until 1986. The Nobel laureate Renato Dulbecco and others proposed at that time that the world scientific community be mobilized to undertake the sequencing of the entire human genome. One motive was to detect DNA damage in people who had survived the atomic bomb attacks and been exposed to radiation in Japan during World War II. But in order to detect changes in the human genome, scientists first needed to know its sequence.

The result was the publicly funded [Human Genome Project](#), an enormous undertaking that was successfully completed in 2003. This effort was aided and complemented by privately funded groups. The genome project benefited from the development of many new methods that were first developed to sequence smaller genomes—those of prokaryotes and simple eukaryotes, the model organisms you have encountered in earlier chapters of this book. Many of these methods are still applied widely, and powerful new methods for sequencing genomes have emerged. These methods are complemented by new ways to examine phenotypic diversity in a cell's proteins and in the metabolic products of the cell's enzymes.

Human Genome Project A publicly and privately funded research effort, successfully completed in 2003, to produce a complete DNA sequence for the entire human genome.

Many prokaryotes have a single chromosome, whereas eukaryotes have many. Because of their differing sizes, chromosomes are easy to separate from one another. You might think that the straightforward way to sequence a chromosome would be to start at one end and simply sequence the DNA molecule one nucleotide at a time. The task is somewhat simplified because only one of the two strands needs to be sequenced, the other being complementary. So if you have the sequence

5' AAGCTCA.....3'

you know that the other strand must be

3' TTCGAGT 5.....'.

But sequencing a DNA molecule millions of bp long from one end to the other is just not possible using current methods. At most, about a few thousand bp can be sequenced at a time using current methods. The key to determining genome sequences is to break up long chromosomes into smaller DNA fragments and then thousands of fragments are sequenced individually at the same time.

In the 1970s Frederick Sanger and his colleagues invented a way to sequence DNA by using chemically modified nucleotides that were originally developed to stop cell division in cancer. This method, or a variation of it, was used to obtain the first human genome sequence as well as those of several model organisms. However, it was relatively slow, expensive, and labor-intensive. The first decade of the new millennium saw the development of faster and less expensive methods, often referred to under the general term **high-throughput sequencing**. These methods use miniaturization techniques first developed for the electronics industry, as well as the principles of DNA replication, often in combination with the ***polymerase chain reaction (PCR)**.

high-throughput sequencing Rapid DNA sequencing on a micro scale in which many fragments of DNA are sequenced in parallel.

High-throughput sequencing methods are rapidly improving. Just one of the many approaches is outlined here and illustrated in **Figure 17.1**. First the DNA is prepared for sequencing by attaching it to a solid surface and amplifying the DNA by PCR (see **Figure 17.1A**):

Figure 17.1 DNA Sequencing High-throughput sequencing involves (A) the chemical amplification of DNA fragments and (B) the synthesis of complementary strands using fluorescently labeled nucleotides.

Animation 17.1 Sequencing the Genome www.Life11e.com/a17.1

Animation 17.2 High-Throughput Sequencing www.Life11e.com/a17.2

- A large molecule of DNA is cut into small fragments of about 100 bp each. This can be done physically, using mechanical forces to shear (break up) the DNA, or by using enzymes that hydrolyze the phosphodiester bonds between nucleotides at intervals in the DNA backbone.
- The DNA is denatured by heat, breaking the hydrogen bonds that hold the two strands together. Each single strand acts as a template for the synthesis of new, complementary DNA.
- Short, synthetic oligonucleotides are attached to each end of each fragment, and these are attached to a solid support.
- The DNA is amplified by PCR using primers complementary to the synthetic oligonucleotides attached to the ends of each DNA. The multiple (approximately 1,000) copies of the DNA at a single location allow for easy detection of added nucleotides during the sequencing steps.

Once the DNA has been attached to a solid substrate and amplified, it is ready for sequencing (see [Figure 17.1B](#)):

- At the beginning of each sequencing cycle, the fragments are heated to denature them. A solution containing a universal primer (complementary to one of the same synthetic oligonucleotides used for the PCR amplification step), DNA polymerase, and the four deoxyribonucleoside triphosphates (dNTPs: dATP, dGTP, dCTP, and dTTP) is then added to the DNA. Recall that dNTPs are the substrates that the DNA polymerase uses in DNA synthesis (see [Key Concept 13.3](#)). Each of the four kinds of dNTP is tagged with a different colored fluorescent dye.
- The DNA synthesis reaction is set up so that only one nucleotide is added to the new DNA strand in each sequencing cycle. After each addition, the unincorporated dNTPs are removed.
- The fluorescence of the new nucleotide at each location is detected with a camera. The color of the fluorescence indicates which of the four nucleotides was added.
- The fluorescent tag is removed from the nucleotide that is already attached, and then the DNA synthesis cycle is repeated. Images are captured after each nucleotide is added. The series of colors at each location indicate the sequence of nucleotides in the growing DNA strand at that location.

The power of this method derives from the fact that:

It is fully automated and miniaturized.

Millions of different fragments are sequenced at the same time.

It is an inexpensive way to sequence large genomes. For example, at the time of this writing, a complete human genome could be sequenced in less than a day for \$1,000. This is in contrast to the Human Genome Project, which took 13 years and \$2.7 billion to sequence one genome!

Sequencing millions of short DNA fragments is only part of the process of constructing the genome. Once these sequences have been determined, they need to be put together in the correct order. That is, they need to be arranged to reflect the sequence of the chromosomes from which they came. Imagine if you cut out every word in this book (there are more than half a million of them), put them on a table, and tried to arrange them in their original order! The enormous task of determining DNA sequences is possible because the original DNA fragments are overlapping.

Let's illustrate the process using a single 10-bp DNA molecule. (This is a double-stranded molecule, but for convenience we show only the sequence of one strand.) The molecule is cut three ways (for example, using three different restriction enzymes). Cutting with the first enzyme generates the fragments:

TG, ATG, and CCTAC

Cutting the same molecule with the second enzyme generates the fragments:

AT, GCC, and TACTG

Cutting with the third enzyme results in:

CTG, CTA, and ATGC

Can you put the fragments in the correct order? (The answer is ATGCCTACTG.) For genome sequencing, the sequence fragments are called "reads" ([Figure 17.2](#)). Of course, the problem of ordering 2.5 million fragments from human chromosome 1 (246 million bp) is more challenging than our 10-bp example above! The field of [bioinformatics](#) was developed to analyze DNA sequences using sophisticated mathematics and computer programs to handle the large amounts of data generated in genome sequencing.

Figure 17.2 Arranging DNA Fragments A series of different cuts is used to generate overlapping DNA fragments. Their sequences are arranged in order by computers. Millions of short segments are arranged in this way to generate the complete sequence of a genome.

bioinformatics The use of computers and/or mathematics to analyze complex biological information, such as DNA sequences.

Genome sequences yield several kinds of information

New genome sequences are being published at an accelerating pace, creating a torrent of biological information. This information is used in two related fields of research, both focused on studying genomes. In **functional genomics**, biologists use sequence information to identify the functions of various parts of genomes (the meaningful sequences in genomes such as those encoding mRNA, tRNA, and regulatory sequences; see [Key Concept 14.4](#)). These parts include:

functional genomics The assignment of functional roles to the proteins encoded by genes identified by sequencing entire genomes.

Open reading frames, which are the coding regions of genes. For protein-coding genes, these regions can be recognized by the start and stop codons for translation, and by recognition sequences that indicate the locations of introns. A major goal of functional genomics is to understand the function of every open reading frame in each genome.

Amino acid sequences of proteins, which can be deduced by applying the genetic code to the DNA sequences of open reading frames.

Regulatory sequences, such as promoters, enhancers, and terminators for transcription. These are identified by their proximity to open reading frames and because they contain recognition sequences for the binding of specific transcription factors.

RNA genes, including rRNA, tRNA, small nuclear RNA, and microRNA genes.

Other noncoding sequences that can be classified into various categories, including centromeric and telomeric regions, transposons, and other repetitive sequences.

Sequence information is also used in **comparative genomics**: the comparison of a newly sequenced genome (or parts thereof) with sequences from other organisms. The Dog Genome Project described at the opening of this chapter, for example, has yielded information not only about dogs, but on how the dog genome compares with other animal genomes. Genome comparisons can provide further information about the functions of sequences and can be used to trace evolutionary relationships among different species. Each animal genome sequenced offers new insights. **Investigating Life: Comparative Analysis of the Tiger Genome** describes the recent sequencing of the tiger genome and how it relates to the genomes of other cats and other mammals.

comparative genomics Computer-aided comparison of DNA sequences between different organisms to reveal genes with related functions.

17.1 recap

The sequencing of genomes involves cutting chromosomes into fragments, sequencing the fragments, and then assembling the fragment sequences into continuous sequences for entire chromosomes. Current sequencing methods use automation and powerful computers. These methods use labeled nucleotides that are detected at the ends of growing polynucleotide chains.

learning outcomes

You should be able to:

- Explain why overlapping sequence fragments are essential in sequencing genomes and how they are arranged to give the final sequence.
- Identify the characteristics of open reading frames.
- Describe examples of comparative genomics.

1. In sequencing genomes, why are overlapping sequences obtained, and how are they arranged to give the final sequence?
2. How are open reading frames recognized in a genomic sequence? What kind of information can be derived from an open reading frame?
3. What is comparative genomics? Give an example of how it is used.

The first genomes to be fully sequenced were those of viruses and prokaryotes. Next we will discuss the information provided by the relatively simple prokaryotic genomes.

the Tiger Genome

experiment

Original Paper: Cho, Y. S. et al. 2013. The tiger genome and comparative analysis with lion and snow leopard genomes. *Nature Communications* 4: 1–7.

Panthera tigris, the tiger, is possibly the most famous endangered species. Fewer than 4,000 individuals remain in the wild. While a century ago there were nine recognized genetically distinct subspecies, four have become extinct. The five extant subspecies include the Bengal tiger seen at zoos and the white Amur tiger that lives in snowy regions of Russia, China, and North Korea. While the genomes of other cats, such as the lion, snow leopard, and domestic cat, had already been sequenced, that of the tiger had not until this study.

HYPOTHESIS▶ Sequencing the genomes of big cats will reveal that the adaptive phenotypic variation seen between cats is due to genetic variation.

METHOD

RESULTS

The tiger genome (20,226 protein-coding genes) and the domestic cat genome (22,285 protein-coding genes) showed a 95.6 percent sequence similarity.

The big cat genomes showed 1,376 mutations for potentially increased function. Some of the mutations were in genes encoding muscle protein development.

CONCLUSION▶ What would you conclude about the phenotype of big cats? Explore the possibilities in the following work with the data.

work with the data

An international team led by Jong Bhak at the Genome Research Foundation in Suwon, South Korea, determined the sequence of tiger DNA and compared it with lion and snow leopard DNA, as well as that of the domestic cat.

QUESTIONS

- The overall sequence of tiger DNA was compared with that of the domestic cat. For reference, a comparison between the human and gorilla genomes was included. Evolutionary distances (last common ancestor) were also estimated. The results are shown in the table. What can you conclude about the rate of evolutionary change between the two cat genomes and between the human and gorilla genomes?

Comparison groups	Last common ancestor (millions of years ago)	Genome sequence similarity (%)
Domestic cat and tiger	10.8	95.6
Human and gorilla	8.8	94.8

- While there are 20,226 protein-coding genes in the tiger genome, some of them are in gene families. That is, some genes are highly similar to one another with the same function. There are 14,528 protein-coding genes in the tiger genome. The research team looked up the genome sequences of other mammals and asked whether the gene families identified in the tiger genome are also present in those other species. The genomics comparisons are shown in the Venn diagram. The number in an overlapping region represents the number of gene families shared with an overlapping genome. For example, the tiger and the domestic cat genomes share 99 gene families with the opossum genome.
 - Looking at the Venn diagram, how many gene families are shared by all the mammalian genomes examined?
 - How many gene families are unique to the tiger and domestic cat genomes? How many are unique to the human and mouse genomes?
 - What do these data indicate about the basic mammalian genome?

- The tiger genome was analyzed for sequences of protein-coding genes of known function. The following types of genes were found in relatively higher numbers compared to the domestic cat:
 - Olfactory (smell) receptors: 289 genes
 - G protein-linked signaling complexes: 302 genes
 - Signal transduction: 295 genes
 - Protein metabolism: 220 genes

What do these genotype data indicate about the phenotype of the tiger?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

***connect the concepts** PCR can be automated and is a key to sequencing small amounts of DNA. Learn about PCR in [Key Concept 13.5](#).

17.2 Prokaryotic Genomes Are Compact

In 1968 Robert W. Holley, was awarded the Nobel Prize for the first sequencing of a nucleic acid—a tRNA with just 80 bases. It took Holley and his team 5 years to discover the sequence. A few years later the first genome was sequenced, that of a 5,386-bp bacteriophage. As methods gradually improved, the genome of a prokaryote was sequenced in the 1990s. With the new automated sequencing techniques we just described, we now have genome sequences for many prokaryotes, to the great benefit of microbiology and medicine.

focus your learning

- Prokaryotes have small, compact genomes.
- Metagenomics allows biologists to sample genomic diversity without isolating intact organisms.
- Transposable elements can move from place to place in the genome.

Prokaryotic genomes have distinctive features

- Bacterial and archaeal genomes have several notable features:
- They are relatively small.* Prokaryotic genomes range from about 160,000 to 12 million bp and are usually organized into a single chromosome.
 - They are compact.* Typically, more than 85 percent of the DNA is in protein-coding sequences or RNA genes, with only short sequences between genes.
 - Prokaryotic gene sequences usually are not interrupted by introns.* An exception is the rRNA and tRNA genes of archaea, which frequently contain introns.
 - In addition to the main chromosome, prokaryotes often have smaller, circular molecules of DNA called plasmids,* which may be transferred between cells (see [Key Concept 12.6](#)).
- Beyond these similarities, there is great diversity among these single-celled organisms, reflecting the huge variety of environments in which they are found (described in [Chapter 25](#)). Let's examine prokaryotic genomes in terms of functional and comparative genomics.

FUNCTIONAL GENOMICS

As we described in [Key Concept 17.1](#), functional genomics is the biological discipline that assigns functions to the products of gene sequences. You can see the various functions encoded by the genomes of three prokaryotes in [Table 17.1](#). As an example, look at the first bacterial genome sequenced, that of *Haemophilus influenzae*, which lives in the human respiratory tract and can cause ear infections or, more seriously, meningitis in children. Its single circular chromosome has 1,830,138 bp. In addition to its origin of replication and the genes coding for rRNAs and tRNAs, this bacterial chromosome has 1,727 open reading frames with promoters nearby.

table 17.1 Gene Functions in Three Bacteria			
Number of genes in:			
Category	<i>E. coli</i>	<i>H. influenzae</i>	<i>M. genitalium</i>

Total protein-coding genes	4,288	1,727	482
Biosynthesis of amino acids	131	68	1
Biosynthesis of cofactors	103	54	5
Biosynthesis of nucleotides	58	53	19
Cell envelope proteins	237	84	17
Energy metabolism	243	112	31
Intermediary metabolism	188	30	6
Lipid metabolism	48	25	6
DNA replication, recombination, and repair	115	87	32
Protein folding	9	6	7
Regulatory proteins	178	64	7
Transcription	55	27	12
Translation	182	141	101
Uptake of molecules from the environment	427	123	34

When the *H. influenzae* sequence was first announced 20 years ago, only 1,007 (58 percent) of the open reading frames coded for proteins with known functions. Since then, scientists have identified the functions of the rest of the encoded proteins. All of the major biochemical pathways and molecular functions are represented. For example, the genes that encode enzymes involved in glycolysis, fermentation, and electron transport have been identified. Gene sequences that code for membrane proteins have been identified as well, including those involved in active transport. An important finding was that highly infective strains of *H. influenzae*—*but* not noninfective strains—have genes for surface proteins that attach the bacterium to the human respiratory tract. These surface proteins are now a focus of research on possible treatments for *H. influenzae* infections.

COMPARATIVE GENOMICS

Soon after the sequence of *H. influenzae* was announced, smaller (*Mycoplasma genitalium*: 580,073 bp) and larger (*E. coli*: 4,639,221 bp) prokaryotic sequences were completed. Thus began the era of comparative genomics. Scientists can identify genes that are present in one bacterium and missing in another, allowing them to relate these genes to bacterial function.

M. genitalium, for example, lacks enzymes needed to synthesize amino acids, whereas *E. coli* and *H. influenzae* both possess such enzymes. This finding reveals that *M. genitalium* must obtain all its amino acids from its environment (usually the human urogenital tract). Furthermore, *E. coli* has 55 genes that encode transcriptional activators, whereas *M. genitalium* has only 12. This relative lack of control over gene expression suggests that the biochemical flexibility of *M. genitalium* must be limited compared with that of *E. coli*.

The sequencing of prokaryotic and viral genomes has many potential benefits

Prokaryotic genome sequencing is providing insights into microorganisms that are important for agriculture and medicine. Scientists who analyze the sequences have discovered previously unknown genes and proteins that can be targeted for isolation and functional study. They have also discovered surprising relationships between some organisms, suggesting that genes may be transferred between different groups.

Rhizobium species are bacteria that form symbiotic associations with plants, living inside the roots of legumes such as beans, peas, and clover. The bacteria fix atmospheric nitrogen from the air and convert it into forms usable by the plants, reducing the need for nitrogen-containing fertilizers. Genome sequences from several *Rhizobium* species have been used to identify the

genes involved in successful symbiosis, and this knowledge is being used both to improve the efficiency of this process and to broaden the range of plants that can form these beneficial associations.

E. coli strain O157:H7 causes illness (sometimes severe) in at least 70,000 people a year in the United States. Its genome has 5,416 genes, of which 1,387 are different from those in the familiar (and harmless) laboratory strains of this bacterium. Many of these unique genes are also present in other pathogenic bacteria, such as *Salmonella* and *Shigella*. This finding suggests that there is extensive genetic exchange among these species, and indeed, “superbugs” that have acquired multiple genes for antibiotic resistance are already a major problem. Sequencing of a particular strain of *E. coli* causing food-borne illness, and comparisons of that sequence with the bacterium in different lots of meat, for example, can allow scientists to pinpoint the meat causing the infection.

Severe acute respiratory syndrome (SARS) was first detected in southern China in 2002 and rapidly spread in 2003. There is no effective treatment, and 10 percent of infected people die. Isolation of the causative agent, a virus, and the rapid sequencing of its genome revealed several novel proteins that are possible targets for antiviral drugs or vaccines. Research is under way on both fronts, since further outbreaks of this and other newly revealed pathogens are anticipated.

Some archaean prokaryotes, such as *Methanobrevibacter*, produce methane gas (CH₄) in the stomachs of cows and other ruminants. By contrast, certain bacterial species, such as *Methylococcus*, remove methane from the air and use it as an energy source. The genomes of both of these prokaryotes have been sequenced. Understanding the genes involved in methane production and consumption is stimulating thinking about ways to slow the progress of global warming, given that methane is the second most prevalent greenhouse gas emitted in the United States and a significant contributor to climate change (see [Key Concept 53.1](#)).

Metagenomics allows us to describe new organisms and ecosystems

If you take a microbiology laboratory course you'll learn how to identify various prokaryotes on the basis of their growth on particular artificial media. For example, staphylococci are a group of bacteria that infect skin and nasal passages. When grown on a medium called blood agar, they form round, raised colonies. Microorganisms can also be identified by their nutritional requirements or the conditions under which they will grow (for example, aerobic versus anaerobic). Such culture methods have been the mainstay of microbial identification for more than a century and are still useful and important. However, scientists can now use PCR and DNA sequencing to identify microbes without culturing them in the laboratory.

In 1985 Norman Pace, then at Indiana University, came up with the idea of isolating DNA directly from environmental samples. He used PCR to amplify specific rRNA-encoding sequences from the samples to determine whether particular microbes were present. The PCR products were sequenced to explore their diversity. The term [metagenomics](#) was coined to describe this approach of analyzing genes without isolating the intact organism. It is now possible to sequence DNA samples from almost any environment. The sequences can be used to detect the presence of both known microbes and heretofore unidentified organisms ([Figure 17.3](#)). For example:

metagenomics The practice of analyzing DNA from environmental samples without isolating intact organisms.

Figure 17.3 Metagenomics Microbial DNA extracted from the environment can be sequenced and analyzed. This has led to the description of many new genes and species.

Sequencing of DNA from 200 liters of seawater indicated that it contained 5,000 different viruses and 2,000 different bacteria, many of which had not been described previously.

One kilogram of marine sediment contained 1 million different viruses, most of them new.

Water runoff from a mine contained many previously unknown species of prokaryotes thriving in what was previously thought of as an inhospitable environment. Some of these organisms exhibited metabolic pathways that were previously unknown to biologists. These organisms and their capabilities may be useful in cleaning up pollutants from the water.

Gut samples from 124 Europeans revealed that each person harbored at least 160 species of bacteria (making up their gut microflora, or ***microbiome**). Many of these species were found in all individuals, but the presence of other bacteria varied from person to person. Such variations may be associated with obesity or bowel diseases.

These and other discoveries are truly extraordinary and potentially very important. It is estimated that 90 percent of the microbial world has been invisible to biologists and is only now being revealed by metagenomics. Entirely new ecosystems of bacteria and viruses are being discovered in which, for example, one species produces a molecule that another metabolizes. It is hard to overemphasize the importance of such an increase in our knowledge of the hidden world of microbes. This knowledge will help us understand natural ecological processes, and has the potential to help us find better ways to manage environmental catastrophes such as oil

spills, or to remove toxic heavy metals from soil.

Some sequences of DNA can move about the genome

As we mentioned in [Key Concept 15.1](#), **transposable elements** (or **transposons**) are segments of DNA that can move from place to place in the genome. Genome sequencing has allowed scientists to study these elements more broadly, and they are now known to be widespread in both prokaryotes and eukaryotes. Prokaryotic transposable elements are often short sequences of 1,000 to 2,000 bp, and they can be found both in chromosomes and in plasmids. A transposable element might be at one location in the genome of one *E. coli* strain, and at a different location in another strain. The insertion of this movable DNA sequence from elsewhere in the genome into the middle of a protein-coding gene can disrupt that gene ([Figure 17.4A](#)). In a prokaryote, the mRNA transcribed from the disrupted gene will contain the extra sequence, and the protein it expresses will be altered and almost certainly nonfunctional. So in prokaryotes transposable elements can produce significant phenotypic effects. Sometimes, two transposable elements located near one another (within a few thousand bp) will transpose together and carry the intervening DNA sequence with them, creating what is called a **composite transposon** ([Figure 17.4B](#)). Genes for antibiotic resistance can be multiplied and transferred between bacteria in this way: composite transposons carrying genes for antibiotic resistance can insert into a plasmid that then moves between bacteria by conjugation (see [Figure 12.22](#)).

transposable element (transposon) A segment of DNA that can move to, or give rise to copies at, another locus on the same or a different chromosome.

composite transposon Two transposable elements located near one another that transpose together and carry the intervening DNA sequence with them. (See transposable element.)

(A) A simple transposon disrupts a coding sequence

(B) A composite transposon inserts an additional coding sequence

Figure 17.4 DNA Sequences That Move Transposable elements are DNA sequences that move from one location to another. (A) In one method of transposition (“copy and paste”), the DNA sequence is replicated and the copy inserts elsewhere in the genome. (B) Composite transposons contain additional genes flanked by two transposable elements.

Q: One hypothesis for the origin of some transposons is through a retroviral infection. Based on what you know of the life cycle of a retrovirus (see [Key Concept 16.3](#)), how might this occur?

As you saw in [Chapter 15](#), there are several ways for transposable elements to move around the genome. For example, a transposable element may be replicated, and then the copy can be inserted into another site in the genome (the “copy and paste” mode). Or the element might splice out of one location and move to another location (“cut and paste”). Transposable elements usually carry genes for enzymes such as transposases, which catalyze the reactions needed for transposition. Often the elements are flanked by inverted repeat DNA sequences that are recognized by these enzymes.

Will defining the genes required for cellular life lead to artificial life?

When we compare the genomes of prokaryotes and eukaryotes, a striking conclusion arises: certain genes are present in all organisms (universal genes). Not surprisingly, these include genes whose products are involved in DNA replication, transcription, and RNA translation to form proteins. There are also some (nearly) universal gene segments that are present in many genes in many organisms; for example, the sequence that codes for an ATP binding site in a protein. These findings suggest that there is some ancient, minimal set of DNA sequences that is common to all cells. One way to identify these sequences is to look for them in computer analyses of sequenced genomes.

Another way to define the minimal genome is to take an organism with a simple genome and deliberately mutate one gene at a time to see what happens. *M. genitalium* has one of the smallest known genomes—only 482 protein-coding genes. Even so, some of its genes are dispensable under some circumstances. For example, *M. genitalium* has genes for metabolizing both glucose and fructose, but it can survive in the laboratory on a medium containing only one of these sugars. Under such conditions it doesn’t need the genes for metabolizing the other sugar.

What about other genes? A team led by Craig Venter has addressed this question with experiments involving the use of transposons as mutagens. When transposons in the bacterium are activated, they insert themselves into genes at random, mutating and inactivating them ([Figure 17.5](#)). The mutated bacteria are tested for growth and survival, and DNA from

interesting mutants is sequenced to find out which genes contain transposons. The astonishing result of these studies is that *M. genitalium* can survive in the laboratory with a minimal genome of only 382 protein-coding genes! In yeast, the minimal genome has been found to consist of only about 10 percent of the 5,000 protein-coding genes; in the nematode *Caenorhabditis elegans*, it is a similar proportion.

Figure 17.5 Using Transposon Mutagenesis to Determine the Minimal Genome

Glass, J. I., N. Assad-Garcia, N. Alperovich, S. Yooseph, M. R. Lewis, M. Maruf, C. A. Hutchison III, H. O. Smith and J. C. Venter. 2006. Essential genes of a minimal bacterium. *Proceedings of the National Academy of Sciences USA* 103: 425–430.

Mycoplasma genitalium has one of the smallest known genomes of any prokaryote. But are all of its genes essential to life? By inactivating the genes one by one, scientists determined which of them are essential for the cell's survival.

HYPOTHESIS ▶ Only some of the genes in a bacterial genome are essential for cell survival.

METHOD

RESULTS

CONCLUSION ▶ If each gene is inactivated in turn, a "minimal essential genome" can be determined.

One goal of this research is to design new life forms with specific purposes, such as bacteria that will clean up oil spills. You'll learn about this approach, called synthetic genetics, in the next chapter.

17.2 recap

DNA sequencing is used to study the genomes of prokaryotes that are important to humans and to ecosystems. Functional genomics uses gene sequences to determine the functions of the gene products. Comparative genomics compares gene sequences from different organisms to help identify their functions and evolutionary relationships. Transposable elements, including composite transposons, move from one place to another in the genome. Studies of the minimal genome may lead to the creation of artificial species.

learning outcomes

You should be able to:

- Describe the characteristic features of prokaryotic genomes
 - Develop experimental approaches to address metagenomic questions.
 - Summarize the ways in which transposable elements can move about the genome.
-
1. Suggest evolutionary reasons to explain why prokaryotic genomes are small, sometimes contain plasmids, and have genes that move about the genome.
 2. How do transposons move about the genome?
 3. There are many bacterial species on the skin of the human belly button. How would you use metagenomics to develop a microbial "fingerprint"?

Advances in DNA sequencing and sequence analysis have led to the rapid sequencing of eukaryotic genomes. We will now look at some of the new insights that have come from these studies.

***connect the concepts** Learn more about how disruptions of the human microbiome are associated with various autoimmune diseases in [Key Concept 25.3](#).

17.3 Eukaryotic Genomes Contain Many Types of Sequences

Eukaryotic and prokaryotic genomes differ in significant ways. Consider, for example, how the bacterial genomes in [Table 17.2](#) compare with those of yeasts, plants, and animals—all eukaryotes. Key differences include the following:

table 17.2 Representative Sequenced Genomes				
Organism	Haploid genome size (Mb) ^a	Number of protein-coding genes	Percent of genome that codes for proteins	Notable attributes
Bacteria				
<i>Mycoplasma genitalium</i>	0.58	482	88	Minimal genome
<i>Haemophilus influenzae</i>	1.83	1,727	89	
<i>Escherichia coli</i>	4.6	4,288	88	Well-studied enteric bacterium
Yeasts				Targeting; cell organelles
<i>Saccharomyces cerevisiae</i>	12.2	6,275	70	
<i>Schizosaccharomyces pombe</i>	13.8	4,824	60	
Plants				Photosynthesis; cell walls
<i>Arabidopsis thaliana</i>	125	27,416	25	Small plant genome
<i>Oryza sativa</i> (rice)	420	40,838	12	Water tolerance for roots
<i>Glycine max</i> (soybean)	973	46,430	7	Lipid synthesis, storage
Animals				
<i>Caenorhabditis elegans</i> (nematode)	100	13,918	25	Tissue formation
<i>Drosophila melanogaster</i> (fruit fly)	140	13,918	13	Embryonic development
<i>Homo sapiens</i> (human)	3,200	~21,000	1.2	Language

^a = Millions of base pairs

Eukaryotic genomes are larger than those of prokaryotes, and they have more protein-coding genes. This difference is not surprising given that multicellular organisms have many cell types with specialized functions. As we saw above, the simple prokaryote *Mycoplasma* has several hundred protein-coding genes in a genome of 0.58 million bp. A rice plant, in contrast, has almost 55,986 genes!

Eukaryotic genomes have more regulatory sequences— and encode many more regulatory proteins—than prokaryotic genomes. The greater complexity of eukaryotes requires much more regulation, which is evident in the many points of control associated with the expression of eukaryotic genes (see [Figure 16.7](#)).

Much of eukaryotic DNA is noncoding. Distributed throughout many eukaryotic genomes are various kinds of DNA sequences that are not transcribed into mRNA, most notably introns and gene control sequences. As we discussed in [Chapter 16](#), some noncoding sequences are transcribed into microRNAs. In addition, eukaryotic genomes contain various kinds of repeated sequences. Prokaryotes, in contrast, seldom contain long noncoding and repeated sequences.

Eukaryotes have multiple chromosomes, whereas prokaryotes usually have a single, circular chromosome. As we have described in previous chapters, eukaryotic chromosomes have multiple origins of replication, a centromere region that holds the replicated chromosomes together before mitosis, and a telomeric sequence at each end of the chromosome that maintains chromosome integrity (**Focus: Key Figure 17.6**).

focus: key figure

Figure 17.6 The Genomic Book of Life Genome sequences contain many features, some of which are summarized in this overview. Sifting through all the information contained in a genome sequence can help us understand how an organism functions and what its evolutionary history might be.

Q: Does increasing genome size necessarily mean that there are more protein-coding genes?

focus your learning

- Nematodes are useful model organisms for studying eukaryotic development.
- Arabidopsis* is an important plant model.
- Gene families result from gene duplications and evolutionary divergence.
- Some moderately repetitive sequences are transcribed but others are not.

Genome sequences of model organisms provide important information

Most of our information about eukaryotic genomes has come from model organisms that have been studied extensively: the yeast *Saccharomyces cerevisiae*, the nematode (roundworm) *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster*, and the thale cress plant (*Arabidopsis thaliana*). Model organisms have been chosen because they are relatively easy to grow and study in a laboratory, their genetics are well studied, and they exhibit characteristics that represent a larger group of organisms.

YEAST: THE BASIC EUKARYOTIC MODEL

Yeasts are single-celled eukaryotes. Like most eukaryotes, they have membrane-enclosed organelles, such as the nucleus and endoplasmic reticulum, and a haplontic life cycle that alternates between haploid and diploid generations (see [Figure 11.14](#)). So it is not surprising that single-celled yeast has a larger genome with more protein-coding genes than a single-celled bacterium (see [Table 17.2](#)). Gene inactivation studies similar to those carried out for *M. genitalium* (see [Figure 17.6](#)) indicate that fewer than 10 percent of the yeast’s genes are essential to survival. The most striking difference between the yeast genome and that of *E. coli* is the number of genes for targeting proteins to organelles ([Table 17.3](#)). Both of these single-celled organisms appear to use about the same number of genes to perform the basic functions of cell survival. It is the compartmentalization of the eukaryotic yeast cell into organelles that requires it to have many more genes. This finding is direct, quantitative confirmation of something we have known for a century: the eukaryotic cell is structurally more complex than the prokaryotic cell.

table 17.3 Comparison of the Genomes of *E. coli* and *S. cerevisiae*

		
	<i>E. coli</i>	Yeast
Genome length (base pairs)	4,640,000	12,157,000
Number of protein-coding genes	4,288	6,275
Proteins with roles in:		

Metabolism	650	650
Energy production/storage	240	175
Membrane transport	280	250
DNA replication/repair/recombination	115	175
Transcription	55	400
Translation	182	350
Protein targeting/secretion	35	430
Cell structure	180	250

THE NEMATODE: UNDERSTANDING EUKARYOTIC DEVELOPMENT

A simple organism in which to study multicellularity is *Caenorhabditis elegans*, a 1-mm-long nematode (roundworm) that normally lives in the soil. It can also live in the laboratory, where it has become a favorite model organism of developmental biologists (see [Key Concept 19.2](#)). The nematode has a transparent body that develops over 3 days from a fertilized egg to an adult worm made up of nearly 1,000 cells. In spite of its small number of cells, the nematode has a nervous system, digests food, reproduces sexually, and ages. So it is not surprising that an intense effort was made to sequence the genome of this model organism.

The *C. elegans* genome (100 million bp) is 8 times larger than that of the yeast *Saccharomyces cerevisiae* and has 3.3 times as many protein-coding genes (see [Table 17.2](#)). Gene inactivation studies have shown that the worm can survive in laboratory cultures with only 10 percent of these genes. So the minimal genome of the worm is about twice the size of that of the yeast (about 5,000 genes), which in turn is about twelve times the size of the minimal genome for *Mycoplasma*. What do these extra genes do? All cells must have genes for survival, growth, and division. In addition, the cells of multicellular organisms must have genes for holding cells together to form tissues, for cell differentiation, and for intercellular communication. Looking at [Table 17.4](#), you will recognize functions that we discussed in earlier chapters, including gene regulation (see [Chapter 16](#)) and cell communication (see [Chapter 7](#)).

table 17.4 *C. elegans* Genes Essential to Multicellularity

Function	Protein/domain	Number of genes
Transcription control	Zinc finger; homeobox	540
RNA processing	RNA binding domains	100
Nerve impulse transmission	Gated ion channels	80
Tissue formation	Collagens	170
Cell interactions	Extracellular domains; glycotransferases	330

DROSOPHILA MELANOGASTER: RELATING GENETICS TO GENOMICS

The fruit fly *Drosophila melanogaster* is a famous model organism. Studies of fruit flies resulted in the formulation of many basic principles of genetics (see [Key Concept 12.4](#)). More than 2,500 mutations of *D. melanogaster* have been described, and this fact alone was a good reason for sequencing the fruit fly's DNA. The fruit fly is a much larger organism than *C. elegans*, both in size (it has ten times more cells) and complexity, and it undergoes complicated developmental transformations from egg to larva to pupa to adult. [Figure 17.7](#) summarizes the functions of the *Drosophila* genes that have been characterized so far; this distribution is typical of complex eukaryotes.

Figure 17.7 Functions of the Eukaryotic Genome The distribution of gene functions in *Drosophila melanogaster* shows a pattern that is typical of many complex organisms.

ARABIDOPSIS: STUDYING THE GENOMES OF PLANTS

About 250,000 species of flowering plants dominate the land and fresh water. But in the context of the history of life, the flowering plants are fairly young, having evolved only about 200 million years ago. The genomes of some plants are huge—for example, the genome of corn is about 3 billion bp, and that of wheat is 17 billion bp. So although we are naturally most interested in the genomes of plants we use as food and fiber, it is not surprising that scientists first chose to

sequence a simpler flowering plant.

Arabidopsis thaliana, thale cress, is a member of the mustard family and has long been a favorite model organism of plant biologists. It is small (hundreds could grow and reproduce in the space occupied by this page), it is easy to manipulate, and it has a relatively small genome of 125 million bp. The *Arabidopsis* genome has more than 27,000 protein-coding genes (see [Table 17.2](#)), but remarkably, many of these genes are duplicates and probably originated by chromosomal rearrangements. When these duplicate genes are subtracted from the total, about 15,000 unique genes are left—similar to the number of genes found in fruit flies. Indeed, many of the genes found in fruit flies have homologs (related genes) in *Arabidopsis* and other plants, suggesting that plants and animals have a common ancestor.

Arabidopsis does, of course, have some genes that distinguish it as a plant ([Table 17.5](#)). From what you know about plants, you can guess what these are: genes involved in photosynthesis, in the transport of water into the root and throughout the plant, in the assembly of the cell wall, in the uptake and metabolism of inorganic substances from the environment, and in the synthesis of specific molecules used for defense against microbes and herbivores (organisms that eat plants). The plant-specific genes in *Arabidopsis* are also found in the genomes of other plants, including rice (*Oryza sativa*), the first major crop plant whose sequence was determined. Rice is the world’s most important crop; it is a staple in the diet of 3 billion people. Despite its larger genome, rice has a set of genes remarkably similar to those of *Arabidopsis*. More recently the genome of the poplar tree *Populus trichocarpa* was sequenced. This rapidly growing tree is widely used for manufacturing paper and is a potential source of fixed carbon for making fuel. A comparison of four plant genomes shows many genes in common, comprising the basic minimal plant genome ([Figure 17.8](#)).

table 17.5 <i>Arabidopsis</i> Genes Unique to Plants		
Function		Number of genes
Cell wall and growth		42
Water channels		300
Photosynthesis		139
Defense and metabolism		94

Figure 17.8 Plant Genomes Four plant genomes share a common set of approximately 12,000 genes that appear to comprise the minimal plant genome.

Eukaryotes have gene families

For about half of all eukaryotic protein-coding genes, only a single copy will be found in the haploid genome (two copies in somatic cells). But there are multiple copies of most other protein-coding genes, a phenomenon resulting from ***gene duplications** occurring over generations. In some cases, over evolutionary time, different copies of genes have undergone separate mutations, giving rise to groups of closely related genes called **gene families**. Some gene families, such as those encoding the globin proteins that make up hemoglobin, contain only a few members. Other families, such as the genes encoding the immunoglobulins that make up antibodies, have hundreds of members. In the human genome there are about 21,000 protein-coding genes, but 16,000 of these are members of gene families. So only about one-third of the human genes are unique.

The DNA sequences in a gene family are usually different from one another. As long as at least one member encodes a functional protein, the other members may mutate in ways that change the functions of the proteins they encode. During evolution, the availability of multiple copies of a gene allows for selection of mutations that provide advantages under certain circumstances. If a mutated gene is useful, it may be selected for in succeeding generations. If the mutated gene is a total loss, the functional copy is still there to carry out its role.

Let's take a look at one gene family, the globin genes in vertebrates. The globins are components of hemoglobin and myoglobin (an oxygen-binding protein present in muscle). The globin genes all arose long ago from a single common ancestral gene. In humans there are three functional members of the α -globin cluster and five in the β -globin cluster ([Figure 17.9](#)). In adults, each hemoglobin molecule is a tetramer containing two identical α -globin subunits, two identical β -globin subunits, and four heme pigments (see [Figure 3.11](#)).

Figure 17.9 The Globin Gene Family The α-globin and β-globin clusters of the human globin gene family are located on different chromosomes. The genes of each cluster are separated by noncoding "spacer" DNA. The nonfunctional pseudogenes are indicated by the Greek letter psi (ψ). The γ gene has two variants, A_γ and G_γ.

During human development, different members of the globin gene cluster are expressed at different times and in different tissues. This differential gene expression has great physiological significance. For example, hemoglobin that contains γ-globin, a subunit found in the hemoglobin of the human fetus, binds O₂ more tightly than adult hemoglobin does. This specialized form of hemoglobin ensures that in the placenta, O₂ will be transferred from the mother's blood to the developing fetus's blood. Just before birth the liver stops synthesizing fetal hemoglobin and the bone marrow cells take over, making the adult form (2 α and 2 β). Thus hemoglobins with different binding affinities for O₂ are provided at different stages of human development.

In addition to genes that encode proteins, many gene families include nonfunctional **pseudogenes**, which are designated with the Greek letter psi (ψ) (see [Figure 17.9](#)). Pseudogenes result from mutations that cause a loss of function rather than an enhanced or new function. The DNA sequence of a pseudogene may not differ greatly from that of other family members. It may simply lack a promoter, for example, and thus fail to be transcribed. Or it may lack a recognition site needed for the removal of an intron, so that the transcript it makes is not correctly processed into a useful mature mRNA. In some gene families pseudogenes outnumber functional genes. In such cases, there appears to be no evolutionary advantage for the deletion of the pseudogenes, even though they have no apparent function.

pseudogene [Gk. *pseudes*: false] A DNA segment that is homologous to a functional gene but is not expressed because of changes to its sequence or changes to its location in the genome.

Eukaryotic genomes contain repetitive sequences

Eukaryotic genomes contain numerous repetitive DNA sequences that do not code for polypeptides. These are typically not in protein-coding genes, which take up only a small percentage of the DNA. These include highly repetitive sequences, moderately repetitive sequences, and transposons.

Highly repetitive sequences are short (less than 100 bp) sequences that are repeated

thousands of times in tandem (side-by-side) arrangements in the genome. They are not transcribed. Their proportion in eukaryotic genomes varies, from 10 percent in humans to about half the genome in some species of fruit flies. Often they are associated with heterochromatin, the densely packed, transcriptionally inactive part of the genome. Other highly repetitive sequences are scattered around the genome. For example, ***short tandem repeats** (STRs) of 1 to 5 bp can be repeated up to 100 times at a particular chromosomal location. The copy number of an STR at a particular location varies among individuals.

highly repetitive sequences Short (less than 100 bp), nontranscribed DNA sequences, repeated thousands of times in tandem arrangements.

Moderately repetitive sequences are repeated 10 to 1,000 times in the eukaryotic genomes. These sequences include the genes that are transcribed to produce tRNAs and rRNAs, which are used in protein synthesis. The cell makes tRNAs and rRNAs constantly, but even at the maximum rate of transcription, single copies of the tRNA and rRNA genes would be inadequate to supply the large amounts of these molecules needed by most cells. Thus the genome has multiple copies of these genes.

moderately repetitive sequences DNA sequences repeated 10–1,000 times in the eukaryotic genome. They include the genes that code for rRNAs and tRNAs, as well as the DNA in telomeres.

In mammals, four different rRNA molecules make up the ribosome: the 18S, 5.8S, 28S, and 5S rRNAs. (The S stands for Svedberg unit, which is a measure of size.) The 18S, 5.8S, and 28S rRNAs are transcribed together as a single precursor RNA molecule ([Figure 17.10](#)). As a result of several posttranscriptional steps, the precursor is cut into the final three rRNA products, and the noncoding “spacer” RNA is discarded. The sequence encoding these RNAs is moderately repetitive in humans: a total of 280 copies of the sequence are located in clusters on five different chromosomes.

(B) Transcription of multiple rRNA genes

Figure 17.10 A Moderately Repetitive Sequence Codes for rRNA (A) This rRNA gene, along with its nontranscribed spacer region, is repeated 280 times in the human genome, with clusters on five chromosomes. (B) This electron micrograph shows transcription of multiple rRNA genes.

Q: Are there similarities between the process depicted in the photo here and the process of translation via polysome shown in [Figure 14.16](#)?

Apart from the RNA genes, most moderately repetitive sequences are transposons, which, like the prokaryotic transposons we discussed earlier, can move about in the genome. Transposons make up more than 40 percent of the human genome and about 50 percent of the corn genome, but in many other eukaryotes the percentage is smaller (3–10 percent).

[Table 17.6](#) summarizes the major types of transposons in eukaryotes. Retrotransposons fall into three groups, based on the types of repetitive sequences they contain: long terminal repeats (LTRs), long interspersed elements (LINEs), and short interspersed elements (SINEs). Retrotransposons move about the genome in a distinctive way: they are transcribed into RNA, which then acts as a template for new DNA. The new DNA becomes inserted at a new location in the genome. This “copy and paste” mechanism results in two copies of the transposon: one at the original location and the other at a new location. A single type of SINE retrotransposon, the 300-bp Alu element, accounts for 11 percent of the human genome; it is present in a million copies!

table 17.6 Types of Sequences in Eukaryotic Genomes

Category	Transcribed	Translated
Single-copy genes		
Promoters and expression control sequences	No	No
Introns	Yes	No
Exons	Yes	Yes
Moderately repetitive sequences		
rRNA and tRNA genes	Yes	No
Transposons		
I. Retrotransposons		
LTRS	Yes	No
SINEs	Yes	No
LINEs	Yes	Yes
II. DNA transposons	Yes	Yes

Transposons of the fourth type, the DNA transposons, do not use RNA intermediates. Like some prokaryotic transposable elements, they are excised from the original location and become inserted at a new location without being replicated (a “cut and paste” mechanism).

What role do these moving sequences play in the cell? The best answer so far seems to be that transposons are simply molecular parasites that can be replicated. The insertion of a transposon at a new location can have important consequences. For example, the insertion of a transposon into the coding region of a gene results in a mutation (see [Figure 17.5](#)). This phenomenon accounts for rare forms of several genetic diseases in humans, including hemophilia and muscular dystrophy. If the insertion of a transposon takes place in the germ line, a gamete with a new mutation results. If the insertion takes place in a somatic cell, cancer may result.

Sometimes an adjacent gene can be replicated along with a transposon, resulting in a gene duplication. A transposon can carry a gene, or a part of it, to a new location in the genome, shuffling the genetic material and creating new genes. Clearly, transposition stirs the genetic pot in the eukaryotic genomes and thus contributes to genetic variation.

17.3 recap

The genomes of eukaryotes contain more genes than those of prokaryotes. Some of these “additional” genes encode functions associated with the compartmentalization of eukaryotic cells; others are needed to support multicellularity. The genome sequences of model organisms have been compared to identify common features of the eukaryotic genomes, including the presence of abundant regulatory sequences, repetitive sequences, and noncoding DNA. Some eukaryotic genes comprise gene families, which may include members that are mutated and nonfunctional.

learning outcomes

You should be able to:

- Distinguish between the features of genomes or model organisms.
 - Predict why different plant species will differ in the features of their genomes.
 - Provide an evolutionary explanation for how gene families promote further evolution in vertebrates.
 - Summarize why the rRNA and tRNA genes involved in protein synthesis are present in multiple copies.
-
1. Describe the roles of a class of proteins found in *Caenorhabditis elegans* that has few counterparts in yeasts.
 2. What is the importance of gene families for evolution?
 3. Why are there multiple copies of sequences coding for rRNA in the mammalian genome?
 4. The genomes of rice, wheat, and corn are similar to one another and to that of *Arabidopsis*. What processes might explain why these four plants are nevertheless distinguished by unique proteins?

The analysis of eukaryotic genomes has resulted in an enormous amount of useful information, as we have seen. In the next section we will look more closely at the human genome.

***connect the concepts** Several specific examples of gene duplication resulting in gene homologs are discussed in [Chapter 19](#), such as the evolution of remarkable homology across animal species of the Hox genes, which regulate early development.

***connect the concepts** [Key Concept 15.3](#) described how STRs can be used in the identification of individuals (DNA fingerprinting).

17.4 Human Biology Is Revealed through the Genome

Since the first human genome sequences were completed early in the first decade of this millennium, the genomes of many other individuals have been sequenced and published. With the rapid development of sequencing technologies, a human genome can be sequenced for less than \$1,000.

focus your learning

The human genome and its genes exemplify the characteristics of complex eukaryote genomes.

Comparisons of haplotypes of individuals with and without a particular genetic disease can identify loci associated with the disease.

Pharmacogenomics is the study of how an individual's genome affects responses to drugs or other outside agents.

The following are just some of the interesting facts that sequencing of the human genome has brought to light:

Of the 3.2 billion bp in the haploid human genome, only an estimated 1.2 percent (about 21,000 genes) make up protein-coding regions. This was a surprise. Before sequencing began, the diversity of human proteins suggested there might be 80,000 to 150,000 genes in the human genome. The actual number of genes—barely more than in the nematode *C. elegans*—means that posttranscriptional mechanisms (such as alternative splicing) must account for the observed number of proteins in humans. That is, the average human gene must code for several different proteins.

The average human gene has 27,000 bp. Gene sizes vary greatly, from about 1,000 bp to 2.4 million bp. Variation in gene size was expected given that human proteins (and RNAs) vary in size, from 100 to about 5,000 amino acids per polypeptide chain.

Most human genes have many introns. The “average” human gene has eight of them, with an average length of 3,300 bp.

About half of the genome is made up of transposons (see [Table 17.6](#)) and other highly repetitive sequences.

When the genomes of two unrelated individuals of the same species are compared, most of the sequence—about 99.9 percent—is identical. Before you jump to the conclusion that we are all the same, remember that we have 3.2 billion bp, so that 0.1 percent difference is 3 million bp! The main differences are in copy number variations of repeated sequences and single nucleotide polymorphisms (SNPs). And don't forget epigenetic differences as well (see [Key Concept 16.4](#)).

Genes are not evenly distributed over the genome. Chromosome 19 is packed densely with genes, whereas chromosome 8 has long stretches without coding regions. The Y chromosome has the fewest genes (about 230), and chromosome 1 has the most (about 3,000).

Comparative genomics reveals the evolution of the human genome

Comparisons among sequenced genomes from prokaryotes and eukaryotes have revealed some of the evolutionary relationships among genes. Some genes are present in both prokaryotes and eukaryotes, others are only in eukaryotes, and still others are only in animals or only in vertebrates ([Figure 17.11](#)).

Figure 17.11 Evolution of the Genome A comparison of the human and other genomes has revealed how genes with new functions have been added over the course of evolution. Each percentage refers to genes in the human genome. Thus 21 percent of human genes have homologs in prokaryotes and other eukaryotes, 32 percent of human genes occur only in other eukaryotes, and so on.

The genomes of various other primates, including all of the great apes, have now been sequenced. The search is on for a set of human genes that differ from those found in other primates and that make us unique. Chimpanzees are our closest living relatives, sharing nearly 99 percent of our DNA sequence. About 500 protein-coding genes have undergone accelerated ***evolution** in humans and chimpanzees, including genes involved in hearing and brain development. Further analyses of these sequences may reveal genes that distinguish us from other apes, and that “make humans human.”

Other clues about “human” genes have come from sequencing the genomes of ancient human relatives. An international team of scientists led by Svante Pääbo at the Max Planck Institute for Evolutionary Anthropology in Germany has extracted and sequenced DNA from the bones of Neanderthals, who lived in Europe up to 50,000 years ago. The entire Neanderthal genome has been sequenced. It is more than 99 percent identical to our human DNA, justifying the classification of Neanderthals as part of the same genus, *Homo*.

Comparisons of the human and Neanderthal genomes are ongoing and have already revealed several interesting facts:

The gene *MC1R* is involved in skin and hair pigmentation. A point mutation found in Neanderthals but not humans caused lower activity of the MC1R protein when it was introduced into cell cultures. Such lower activity of MC1R is known to result in fair skin and red hair in humans. So it appears that at least some Neanderthals may have had pale skin and red hair.

The gene *FOXP2* is involved in vocalization in many organisms, including birds and mammals. In humans, mutations in this gene result in severe speech impairment. The Neanderthal *FOXP2* gene is identical to that of humans, whereas that of chimpanzees is slightly different. This has led to speculation that Neanderthals were capable of speech.

While the human and Neanderthal genome sequences are very similar, there are differences in many point mutations and larger chromosomal arrangements. There are distinctive “human” DNA sequences and also distinctive “Neanderthal” sequences. There is some mixture of the two, indicating that humans and Neanderthals interbred, with transfer of DNA between the two.

Human genomics has potential benefits in medicine

Most complex phenotypes are determined not by single genes but by multiple genes interacting with the environment. The single-allele explanations of phenylketonuria and sickle-cell anemia (see [Key Concept 15.2](#)) do not apply to such common disorders as diabetes, heart disease, and Alzheimer’s disease. To understand the genetic bases of these diseases, biologists are now using rapid genotyping technologies to create “haplotype maps,” which are used to identify SNPs that are linked to genes involved in disease.

HAPLOTYPE MAPPING

The SNPs that differ among individuals are not inherited as independent alleles. Rather, a set of SNPs that are present on a segment of chromosome are usually inherited as a unit. This linked piece of a chromosome is called a [haplotype](#). You can think of the chromosome segment as a sentence, the haplotype as a word, and the SNP as a letter in the word. Analyzing SNPs is faster and less expensive than sequencing whole genomes, so haplotype mapping provides a shortcut for identifying the locations of genes and mutations involved in particular diseases (see [Key Concept 15.3](#)). By comparing the haplotypes of individuals with and without a particular genetic disease, the genetic loci associated with the disease can be identified ([Figure 17.12](#)).

haplotype Linked nucleotide sequences that are usually inherited as a unit (as a “sentence” rather than as individual “words”).

Figure 17.12 SNP Genotyping and Disease Scanning the genomes of people with and without particular diseases reveals correlations between SNPs and complex

diseases.

A microarray of 500,000 SNPs has been used to analyze thousands of people to find out which SNPs are associated with specific diseases. The amount of data is prodigious: 500,000 SNPs, thousands of people, thousands of medical records. With so much natural variation, statistical measures of association between a haplotype and a disease need to be very rigorous.

GENOTYPING TECHNOLOGY AND PERSONAL GENOMICS

Association tests like the one described in [Figure 17.12](#) have revealed particular haplotypes or alleles that are associated with modestly increased risks for diseases. For example, a particular SNP on chromosome 10 is associated with a 65% increased risk for adult-onset diabetes when heterozygous, and almost three-fold when homozygous. This information can have predictive value in counseling and treating patients. Private companies can now scan a human genome for these variants—and the price for this service keeps getting lower. However, at this point it is unclear what a person without symptoms should do with the information, since multiple genes, environmental influences, and epigenetic effects all contribute to the development of these diseases.

Of course, the most comprehensive way to analyze a person's genome is by actually sequencing it. As the cost of genome sequencing and analysis goes down, SNP testing will be superseded. In 2015 the U.S. government announced a plan to sequence the genomes of 1 million Americans and link the sequences to medical records. This approach is not new, but the large scale of it is. The goal is to relate genome changes to diseases such as cancer and diabetes, and to use these changes for diagnosis and, if they lead to changes in encoded proteins, to therapies targeted at the altered proteins.

PHARMACOGENOMICS

Genetic variation can affect how an individual responds to a particular drug. For example, a drug may be chemically modified in the liver to make it more or less active. Consider an enzyme that catalyzes the following reaction:

A mutation in the gene that encodes this enzyme may make the enzyme less active. For a given dose of the drug, a person with the mutation would have more active drug in the bloodstream than a person without the mutation. So the effective dose of the drug would be lower in the person with the mutation.

Now consider a different case, in which the liver enzyme is needed to make the drug active:

A person carrying a mutation in the gene encoding this liver enzyme would not be affected by the drug, since the activating enzyme is not present.

The study of how an individual's genome affects his or her response to drugs or other outside agents is called [pharmacogenomics](#). Just as it is possible to identify haplotypes or SNPs that are associated with particular disease susceptibilities, it is also possible to identify SNPs that are associated with specific drug responses. This type of analysis makes it possible to predict whether a drug will be effective. The objective is to personalize drug treatment so that a physician can know in advance whether an individual will benefit from a particular drug ([Figure 17.13](#)). This approach might also be used to reduce the incidence of adverse drug reactions by identifying individuals who will metabolize a drug slowly, which can lead to a dangerously high level of the drug in the body.

pharmacogenomics The study of how an individual's genetic makeup affects his or her response to drugs or other agents, with the goal of predicting the effectiveness of different treatment options.

Figure 17.13 Pharmacogenomics Correlations between genotypes and responses to drugs will help physicians develop personalized medical care. The different colors indicate individuals with different SNPs.

17.4 recap

The haploid human genome has 3.2 billion bp, but only about 1.2 percent of the genome codes for proteins. Most human genes are subject to alternative splicing, which may account for why there are more proteins than genes. Haplotype mapping to find correlations of specific SNPs with disease and drug susceptibility holds promise for personalized, precision medicine.

learning outcomes

You should be able to:

- Describe the characteristics of the human genome and its genes.
- Use haplotype information to determine whether a gene is associated with a phenotypic characteristic.
- Summarize the use of pharmacogenomics.

1. How do human cells express a larger number of proteins than is accounted for by the number of protein-coding genes in the human genome?
2. A patient is prescribed a drug whose metabolism in the body is under the control of known genes and alleles. How could haplotype mapping be used to get information on whether this drug would be effective in this patient?

Genome sequencing has advanced our understanding of biology enormously. High-throughput technologies are now being applied to other components of the cell: proteins and metabolites. We will now turn to the results of these studies.

***connect the concepts** How comparisons of primate and human genomes have refined our understanding of human evolution is discussed in [Key Concept 32.5](#).

17.5 Proteomics and Metabolomics Can Provide Insights beyond the Genome

Statements like “The human genome is the book of life” were commonly made at the time the human genome sequence was first revealed, reflecting a belief in “genetic determinism”—that a person’s phenotype is determined by his or her genotype. But as we have repeatedly stressed, an organism is not just a product of gene expression. The proteins and small molecules present in any cell at a given point in time reflect not just gene expression but also the influences of the intracellular and extracellular environments. Complementing genomics, the fields of proteomics and metabolomics have emerged to provide a more complete understanding of the relationship between genome and organism.

focus your learning

Chemical methods are used to identify components of the proteome.

The metabolome is the complete set of small molecules, called metabolites, that are present in the cell.

The proteome is the complete set of proteins in a cell, tissue, or organism at a given time

As mentioned above, many genes encode more than a single protein ([Figure 17.14](#)).

***Alternative splicing** of a given gene can allow different combinations of exons to be transcribed into the mature mRNAs. Posttranslational modifications also increase the number of protein variants that can be derived from one gene. It should also be noted that in a multicellular organism many proteins are produced only by certain cells and only under specific conditions. Even single-celled organisms express only a subset of their genes at any particular time. The **proteome** is the sum total of the proteins produced by a cell, tissue, or organism at a given time, under defined conditions.

Figure 17.14 Proteomics A single gene can code for multiple proteins.

proteome The complete set of proteins that can be made by an organism. Because of alternative splicing of pre-mRNA, the number of proteins that can be made is usually much larger than the number of protein-coding genes present in the organism's genome.

The proteome is analyzed by mass spectrometry, a technique that uses electromagnets to identify proteins by the mass. The ultimate aim of proteomics is just as ambitious as that of genomics. Whereas genomics seeks to describe the genome and its expression, proteomics seeks to identify and characterize all of the expressed proteins.

Comparisons of the proteomes of humans and other eukaryotic organisms have revealed a common set of proteins that can be categorized into groups with similar amino acid sequences and similar functions. When considered on a whole-organism basis, 46 percent of the yeast proteome, 43 percent of the nematode proteome, and 61 percent of the fruit fly proteome are shared by the human proteome. Functional analyses indicate that this set of 1,300 proteins provides the basic metabolic functions of a eukaryotic cell, such as glycolysis, the citric acid cycle, membrane transport, protein synthesis, DNA replication, and so on ([Figure 17.15](#)).

Figure 17.15 Proteins of the Eukaryotic Proteome About 1,300 proteins are common to all eukaryotes and fall into these categories. Although their amino acid sequences may differ to a limited extent, they perform the same essential functions in all eukaryotes.

There are, of course, many uniquely human proteins in addition to those we share with other eukaryotic organisms. As we have mentioned before, proteins have different functional regions called domains (for example, a domain for binding a substrate, or a domain for spanning a membrane). While a particular organism may have many unique proteins, those proteins are often just unique combinations of domains that exist in other organisms. *This reshuffling of the genetic deck is a key to evolution.*

Proteins seldom exist in isolation. Most interact with other molecules, such as nucleic acids (e.g., transcription factors and DNA), other proteins (e.g., the respiratory chain complexes in mitochondria), and lipids (receptors in the cell membrane). A major task of proteomics is

analyzing these interactions.

Metabolomics is the study of chemical phenotype

Studying genes and proteins gives a limited picture of what is going on in a cell. As we have seen, both gene function and protein function are affected by the internal and external environments of the cell. Many proteins are enzymes, and their activities affect the concentrations of their substrates and products. So as the proteome changes, so will the abundances of small molecules called metabolites. The [metabolome](#) is the complete set of small molecules present in a cell, tissue, or organism under defined conditions. These include:

metabolome The quantitative description of all the small molecules in a cell or organism.
--

Primary metabolites involved in normal processes, such as intermediates in pathways such as glycolysis. This category also includes hormones and other signaling molecules.

Secondary metabolites, which are often unique to particular organisms or groups of organisms. They are often involved in special responses to the environment. Examples are antibiotics made by microbes, and the many chemicals made by plants that are used in defense against pathogens and herbivores.

Not surprisingly, measuring metabolites involves sophisticated analytical instruments. If you have studied organic or analytical chemistry, you may be familiar with gas chromatography and high-performance liquid chromatography, which separate molecules, and with mass spectrometry and nuclear magnetic resonance spectroscopy, which are used to identify them. These measurements result in “chemical snapshots” of cells or organisms, which can be related to physiological states.

There has been some progress in defining the human metabolome. A database created by David Wishart and colleagues at the University of Alberta contains more than 6,500 metabolite entries. The challenge now is to relate levels of these substances to physiology. For example, you probably know that high levels of glucose in the blood are associated with diabetes. But what about the early stages of heart disease? There may be a pattern of metabolites that is diagnostic of this disease. This could aid in early diagnosis and treatment.

Plant biologists are ahead of medical researchers in the field of metabolomics. Over the years, tens of thousands of secondary metabolites have been identified in plants, many of them made in response to environmental challenges. Some of these will be discussed in [Chapter 38](#). The metabolome of the model organism *Arabidopsis thaliana* is being described, and will give insight into how a plant copes with stresses such as drought or pathogen attack. This knowledge could be helpful in optimizing plant growth for agriculture.

17.5 recap

The proteome is the set of all proteins produced by a cell, tissue, or organism under specific conditions. The metabolome is the total content of small molecules, such as intermediates in primary metabolism, hormones, and secondary metabolites. The proteome and the metabolome can be analyzed using chemical methods that separate and identify molecules.

learning outcomes

You should be able to:

- Summarize how chemical methods are used in proteomics.

- Provide examples of applications of metabolomic data for human health.

1. How is the proteome analyzed?
2. Why would it be useful to have a database of primary and secondary metabolites involved in human metabolism?

▶ investigatinglife

QA A What have we learned from sequencing animal genomes?

In certain dog breeds, such as whippets, the muscles of some individuals can be much bulkier than is normal. Genome analyses have shown that the gene for myostatin, a protein that inhibits muscle growth, is mutated in whippets that have bulky muscles. When the myostatin gene is mutated, the protein that inhibits muscle growth is dysfunctional ([Figure 17.16](#)). Comparative genomics reveals that the myostatin gene is also mutated in certain breeds of cattle and sheep that are noted for overdeveloped muscles.

Figure 17.16 Muscular Gene These dogs are both whippets, but the muscle-bound dog (right) has a mutation in the myostatin gene.

With the knowledge that myostatin affects muscle development, some consideration has been given to the possibility of manipulating myostatin in humans to treat muscle-wasting diseases such as muscular dystrophy. As you might expect, athletes anxious to have bulkier muscles are also very interested in this gene and its protein product.

Future directions

Few scientific endeavors have received as much hype and hope as genome sequencing. A major effort

is under way to sequence the genomes of tumors in as many people as possible, to screen for mutations. When the *BRCA1* gene was identified as mutated in breast cancer (see [Chapter 15](#)), some medical scientists hoped that cancer would be like other genetic diseases such as sickle-cell anemia—caused by a single mutation in a single gene. So far, the lessons learned from cancer genomes include that there are many mutations in a tumor, and that some of them drive the tumor formation while others do not; that the mutations in one person's tumor of a particular type may differ from those in the same tumor in someone else; and that tumor genomes evolve over time as the tumor grows and spreads. Understanding tumor genomes is not straightforward. Nevertheless, the goal is to study genomes to determine how gene products and the environment interact to form the tumor phenotype, and to design therapy for that tumor in individual people. This is called precision medicine, and it is in the future. It is a model for a goal of genomics: to determine the relationship between genotype, the environment, and phenotype.

► 17.1 Genomes Can Be Sequenced Rapidly

- Methods of DNA sequencing involve miniaturization and computerized analysis. **Review Figure 17.1, Animations 17.1, 17.2**
- Genomes are sequenced in overlapping fragments, and then the fragments are lined up to give the final sequence. **Review Figure 17.2**
- The analysis of genome sequences gives information about protein-coding and noncoding regions.

► 17.2 Prokaryotic Genomes Are Compact

- DNA sequencing is used to study the genomes of prokaryotes that are important to humans and ecosystems.
- **Metagenomics** is the identification of DNA sequences from multiple organisms from a bulk environmental sample (such as soil or seawater). **Review Figure 17.3**

metagenomics The practice of analyzing DNA from environmental samples without isolating intact organisms.

- **Transposable elements** (or **transposons**) and **composite transposons** can move about the genome. **Review Figure 17.4**

transposable element (transposon) A segment of DNA that can move to, or give rise to copies at, another locus on the same or a different chromosome.

composite transposon Two transposable elements located near one another that transpose together and carry the intervening DNA sequence with them. (See transposable element.)

- Transposon mutagenesis can be used to inactivate genes one by one. The mutated organism can be tested for survival and a minimal set of essential genes described. **Review Figure 17.5**

► 17.3 Eukaryotic Genomes Contain Many Types of Sequences

Review Focus: Key Figure 17.6

- Comparisons of genome sequences from model organisms have revealed some common features of the eukaryotic genomes as well as specialized genes for cellular compartmentalization, development, and features unique to plants. **Review Tables 17.2–17.5, Figures 17.7, 17.8**
- Some eukaryotic genes exist as members of **gene families**. Proteins may be made from these closely related genes at different times and in different tissues. Some members of gene families may be nonfunctional **pseudogenes**. **Review Figure 17.9**

pseudogene [Gk. *pseudes*: false] A DNA segment that is homologous to a functional gene but is not expressed because of changes to its sequence or changes to its location in the genome.

- Repeated sequences are present in the eukaryotic genomes. **Review Table 17.6**
- **Moderately repetitive sequences** include those coding for rRNA and transposons. **Review Figure 17.10**

moderately repetitive sequences DNA sequences repeated 10–1,000 times in the eukaryotic genome. They include the genes that code for rRNAs and tRNAs, as well as the DNA in telomeres.

▶ 17.4 Human Biology Is Revealed through the Genome

- The haploid human genome has 3.2 billion bp.
- Only about 1.2 percent of the genome codes for proteins; the rest consists of repeated sequences and noncoding DNA.
- Most human genes have introns, and alternative splicing leads to the production of more than one protein per gene.
- SNP genotyping (haplotype mapping) correlates variations in the genome with diseases or drug sensitivity. It may lead to precision medicine. **Review Figure 17.12**
- **Pharmacogenomics** uses DNA and amino acid sequence data to inform drug development and testing. **Review Figure 17.13**

pharmacogenomics The study of how an individual's genetic makeup affects his or her response to drugs or other agents, with the goal of predicting the effectiveness of different treatment options.

▶ 17.5 Proteomics and Metabolomics Can Provide Insights beyond the Genome

- The **proteome** is the complete set of proteins in a cell, tissue, or organism at a given time.

proteome The complete set of proteins that can be made by an organism. Because of alternative splicing of pre-mRNA, the number of proteins that can be made is usually much larger than the number of protein-coding genes present in the organism's genome.

- There are more proteins than there are protein-coding genes in the genome.
- The proteome can be analyzed using chemical methods that separate and identify proteins.
- The metabolome is the complete set of small molecules present in a cell, tissue, or organism under defined conditions.

Different people metabolize the (hypothetical) antianxiety drug Calm at different rates. This variation is potentially a problem because too-high concentrations of the drug can have harmful side effects, while too-low concentrations may not give the desired therapeutic effect. Knowledge about how genotypes affect the metabolism of Calm would be very useful.

In a study, people who had been genotyped at various single nucleotide polymorphisms (SNPs) across the genome were given Calm. Twelve hours later, they had their blood drawn to assess the concentration of the drug. Individual concentrations were normalized by dividing by the global mean concentration and multiplying by 100. The results for the three SNPs with the greatest effects are shown in the figure below. Note that the double letters correspond to the nucleotides on homologous chromosomes (e. g., “AC” means there is A on one chromosome and C on its homolog).

Questions

1. Describe the relationship between genotype and Calm concentration and between genotype and Calm metabolism for each of the three SNPs.
2. Based on the data, would you recommend a higher dose or a lower dose of the drug for individuals with the AA genotype than for those with the GG genotype at SNP 5689? Explain your answer.
3. Suppose SNP 5689 were at a gene that encoded an enzyme that broke down the drug. Would you expect the enzyme encoded by the A allele of the gene to be more or less active than the enzyme encoded by the G allele? Explain your answer.
1. Suppose SNP 8835 were at a gene that encoded an inhibitor for the enzyme in Question 3. Would you expect the enzyme encoded by the A allele of the gene to be more or less active than the enzyme encoded by the C allele? Explain your answer.
5. The drug Calm appears to affect protein synthesis at several genes in liver tissue. Briefly describe how a medical researcher could examine which proteins have altered expression in a mouse model, highlighting the technique that would be used.

DNA Technology Meets Medicine

Janet was arriving at her office when she first felt numb on the left side of her face. She became confused and had difficulty finding her office. After a passerby called 911, an emergency response team transported Janet to a nearby hospital. She had had a stroke, but amazingly, she was back at work and fully functional two days later.

A stroke can occur when a large blood vessel that supplies the brain with oxygen and nutrients is blocked. Within minutes of blockage, cellular respiration in affected brain cells is reduced, and within minutes to hours, the cells die. Nerves controlling muscles in Janet's face were affected first, followed by brain regions involved in cognitive processes.

Blood vessel blockage is often associated with a blood clot on a fat deposit that has built up on the inner walls of a blood vessel. Janet's tendency to eat fatty foods, coupled with her genetic constitution, led to the formation of fatty deposits in her blood vessels. Ultimately the buildup of these fatty plaques can narrow blood vessels, causing blood clots to form that can block blood flow. Blockage of a vessel that feeds the brain results in a stroke.

Janet was treated with tissue plasminogen activator, or TPA, a protein involved in dissolving blood clots. Your body produces TPA when you have a cut; its action is seen when the clot “goes away” a few days later. Janet's cells would have gradually made TPA to slowly dissolve the clot blocking the vessel to her brain, but in the meantime her brain cells would have died. To speed up the process, Janet was injected with TPA right around the clot.

Where did the TPA used in Janet's treatment come from? TPA is a protein made in tiny amounts by blood vessel cells. Extracting enough TPA from tissues is impractical; recombinant DNA technology is required to get enough of it for therapeutic injection into a bloodstream. As you will learn in Investigating Life: Producing TPA, the process involves inserting the gene that encodes TPA into living bacterial cells in the lab. These cells are then biochemically coaxed into expressing TPA protein in quantity. The production of TPA is but one example of how knowledge of molecular biology and advances in biotechnology have transformed biological research and launched new industries that employ microbes to produce proteins and other useful chemicals.

How is biotechnology changing medicine?

18.1 DNA from Different Sources Forms Recombinant DNA

Recombinant DNA is a DNA molecule that has been made in the laboratory using at least two different sources of DNA. The DNAs used for recombination can be from the same organism (e.g., from different chromosomes), from different members of the same species, or from entirely different organisms.

recombinant DNA A DNA molecule made in the laboratory that is derived from two or more genetic sources.

focus your learning

Recombinant DNA technology uses restriction enzymes and DNA ligase to respectively cut and paste DNA.

Restriction enzymes (***restriction endonucleases**) can cleave double-stranded DNA. In the late 1960s scientists discovered **DNA ligase**, which catalyzes the joining of DNA fragments; one of its functions is to join Okazaki fragments during DNA replication (see [Figure 13.15](#)). With restriction enzymes in hand, scientists saw the potential to cut DNA molecules and then splice the fragments together in new combinations (“recombine” the DNA fragments). In 1973 Stanley Cohen at Stanford University, Herbert Boyer at the University of California, and their colleagues did just that. As illustrated in [Figure 18.1](#), they isolated two different plasmids (small circular DNA molecules that replicate independently of the main chromosome in bacterial cells; see [Figure 12.22](#)) from *Escherichia coli*. Each of the two plasmids contained different antibiotic resistance genes. The scientists cut the two plasmids with restriction enzymes, mixed the fragments together, and then used DNA ligase to rejoin them. The recombinant plasmids of this ligation reaction were then inserted into new *E. coli* cells, and the cells were grown in the presence of both antibiotics. A few of the bacteria had been transformed with a recombinant plasmid containing both of the antibiotic resistance genes and could grow on the medium, whereas no *E. coli* lacking a recombinant plasmid were resistant to both antibiotics. With this experiment, recombinant DNA technology was born.

DNA ligase Enzyme that unites broken DNA strands during replication and recombination.

experiment

Figure 18.1 Can DNA from Two Different Sources Be Recombined into a Single Functional DNA Molecule?

Original Paper: Cohen, S. N., A. C. Y. Chang, H. W. Boyer and R. B. Helling. 1973. Construction of biologically functional bacterial plasmids in vitro. *Proceedings of the National Academy of Sciences USA* 70: 3240–3244.

With the discovery of restriction enzymes and DNA ligase, it became possible to combine DNA fragments from different sources in the laboratory. But would such “recombinant DNA” be functional when inserted into a living cell? The results of this experiment by Stanley Cohen and Herbert Boyer completely changed the scope of genetic research, increasing our knowledge of gene structure and function, and ushered in the new field of biotechnology.

HYPOTHESIS ▶ Biologically functional recombinant plasmids can be made in the laboratory.

Media Clip 18.1 Striking Views of Recombinant DNA Being Made
www.Life11e.com/mc18.1

METHOD

E. coli plasmids carrying a gene for resistance to either the antibiotic kanamycin (K) or tetracycline (T) are cut with a restriction enzyme.

RESULTS

CONCLUSION ▶ Two DNA fragments with different genes can be joined to make a functional recombinant DNA molecule.

A work with the data exercise that accompanies this figure may be assigned in LaunchPad

Let's look more closely at what happens when DNA is cut with a restriction enzyme and then rejoined with DNA ligase. Many restriction enzymes recognize palindromic DNA sequences—sequences that read the same way in both directions. For example, you can read the DNA recognition sequence for the restriction enzyme *EcoRI* from 5' to 3' as GAATTC on both strands:

5'.....GAATTC 3'

3'.....CTTAAG.....5'

Some restriction enzymes cut the DNA straight through the middle of the palindrome, generating “blunt-ended” fragments. Others, such as *EcoRI*, make staggered cuts—they cut the phosphodiester bond of one strand of the double helix several bases away from where they cut the other (**Focus: Key Figure 18.2**). After *EcoRI* makes its two cuts in the complementary strands, the ends of the strands are held together only by the hydrogen bonds between four base pairs. At warm temperatures (above room temperature) these hydrogen bonds are too weak to hold the two strands together, so the DNA separates into fragments when it is warmed. Each fragment carries a single-stranded “overhang” at the location of each cut. These overhangs are called **sticky ends** because they have specific base sequences that can bind by base pairing with complementary sticky ends.

focus: key figure

1 *EcoRI* cuts the two DNA strands at two different points in a palindromic recognition sequence.

EcoRI cuts between G and A at red arrows

2 The separated strands have "sticky ends" with unpaired bases.

3 The sticky ends can hydrogen-bond to complementary sticky ends from other DNAs, and the resulting **recombinant DNA** can be sealed with DNA ligase.

4 Only a small fraction of the products are recombinant. The most common reaction is for the original DNAs to re-form.

Figure 18.2 Cutting, Splicing, and Joining DNA Some restriction enzymes (*EcoRI* is shown here) make staggered cuts in DNA. *EcoRI* can be used to cut two different DNA molecules (blue and orange). The exposed bases can hydrogen-bond with complementary exposed bases on other DNA fragments, forming recombinant DNA. DNA ligase stabilizes the recombinant molecule by forming covalent bonds in the DNA backbone.

Q: If restriction enzymes make blunt (non-sticky) ends in DNA, how can two DNA molecules be spliced together?

sticky ends On a piece of two-stranded DNA, short, complementary, one-stranded regions produced by the action of a restriction endonuclease. Sticky ends facilitate the joining of segments of DNA from different sources.

Any two sticky ends that are complementary can form hydrogen bonds with one another. The sticky ends of the original molecule may rejoin, or two different fragments may join (see [Figure 18.2](#)). Indeed, a fragment from one source, such as a human, can be joined to a fragment from another source, such as a bacterium. Initially the fragments are held together only by weak hydrogen bonds, but the enzyme DNA ligase catalyzes the formation of covalent bonds between adjacent nucleotides at the ends of the fragments, joining them to form a single, larger molecule.

Besides *EcoRI*, there are hundreds of other restriction enzymes, each with its own recognition sequence. With these tools—restriction enzymes and DNA ligase—scientists can cut and rejoin different DNA molecules from any sources, including artificially synthesized DNA sequences. Recently, new tools have been developed for making recombinant DNA. Methods based on the

polymerase chain reaction (PCR) allow the joining of any two DNA molecules without the need for conveniently placed restriction enzyme sites. Despite these advances, restriction enzymes and DNA ligase are still used routinely for recombinant DNA construction in biology labs.

18.1 recap

DNA fragments from different sources can be linked together to make recombinant DNA. DNA can be cut with a restriction enzyme and then rejoined with DNA ligase. There are many different restriction enzymes, each with its own recognition sequence.

learning outcomes

You should be able to:

- Show how staggered cuts in DNA made by restriction enzymes lead to the creation of sticky ends.
- Summarize the Cohen and Boyer experiments on creating recombinant DNA.

1. How does a staggered cut in DNA create a sticky end?
2. How did Cohen and Boyer make the first recombinant DNA?

Recombinant DNA has no biological significance until it is inserted inside a living cell, which can replicate and transcribe the transplanted genetic information. How can recombinant DNA made in the laboratory be inserted and expressed in living cells?

***connect the concepts** As discussed in [Key Concept 15.3](#), restriction endonucleases are a class of enzymes that cut DNA molecules. Each enzyme recognizes a unique sequence of nucleotides in the DNA strand, usually about 4–6 base pairs long.

18.2

There Are Several Ways to Insert DNA 18.2 into Cells

One reason for making recombinant DNA is to **clone**—that is, to produce many identical copies of—a particular gene or other DNA sequence. We have seen the term “clone” used in the context of whole cells or organisms (see [Chapters 11](#) and [12](#)) that are genetically identical to one another. A gene can be cloned by inserting it into a bacterial cell such as *E. coli*. The bacterium is allowed to reproduce and multiply into millions of identical cells, all carrying copies of the gene. Cloning might be done to get enough DNA for sequencing and subsequent analysis, to produce a protein product in quantity, or as a step toward creating an organism with a new phenotype.

clone [Gk. *klon*: twig, shoot] (1) Genetically identical cells or organisms produced from a common ancestor by asexual means. (2) To produce many identical copies of a DNA sequence by its introduction into, and subsequent asexual reproduction of, a cell or organism.

focus your learning

Reporter genes carried by a vector can be used to detect the presence of recombinant DNA in host cells.

Recombinant DNA is cloned by inserting it into host cells in a process known as **transformation**—or **transfection** if the host cells are derived from an animal. (See [Key Concept 13.1](#) for another example of transformation in bacteria.) A host cell or organism that contains recombinant DNA is referred to as a **transgenic** cell or organism, and the non-native DNA is called a transgene. Later in this chapter we will encounter many examples of transgenic organisms, including yeast, rice plants, and even cattle.

transformation (1) A mechanism for transfer of genetic information in bacteria in which pure DNA from a bacterium of one genotype is taken in through the cell surface of a bacterium of a different genotype and incorporated into the chromosome of the recipient cell. (2) Insertion of recombinant DNA into a host cell.

transfection Insertion of recombinant DNA into animal cells.

transgenic Containing recombinant DNA incorporated into the genetic material.

Selectable genetic markers are used to identify host cells containing recombinant DNA

Various methods are used to create transgenic cells. Generally these methods are inefficient in that only a few of the cells that are exposed to the recombinant DNA actually become transformed with it. In order to isolate and reproduce only transgenic cells, **selectable marker** genes, such as genes that confer resistance to antibiotics, are often included as part of the recombinant DNA molecule. When an antibiotic resistance gene is used as the selectable marker, the cells from the transformation experiment are grown in the presence of the antibiotic;

the antibiotic kills all nontransgenic cells, leaving only the transgenic cells. Antibiotic resistance genes were the markers used in Cohen and Boyer's experiment (see [Figure 18.1](#)).

selectable marker A gene, such as one encoding resistance to an antibiotic, that can be used to identify (select) cells that contain recombinant DNA from among a large population of untransformed cells.

Genes can be inserted into prokaryotic or eukaryotic cells

In theory, any cell or organism can act as a host for the introduction of recombinant DNA. Most research has been done using model organisms:

Bacteria are easily grown and manipulated in the laboratory. Much of their molecular biology is known, especially for well-studied bacteria such as *E. coli*. Furthermore, bacteria contain plasmids, which are easily manipulated to carry recombinant DNA into the cell. But since the processes of transcription, translation, and posttranslational modification proceed differently in prokaryotes than they do in eukaryotes, bacteria are not always well suited as hosts to express eukaryotic genes.

Yeasts such as *Saccharomyces cerevisiae* are commonly used as eukaryotic hosts for recombinant DNA studies. The advantages of using yeasts include rapid cell division (a life cycle completed in 2–4 hours), ease of growth in the laboratory, and a relatively small genome size (see [Table 17.2](#)). In addition, yeast cells have most of the characteristics of other eukaryotic cells, with a notable exception being those associated with multicellularity.

Plant cells are good hosts because of their ability to make totipotent ***stem cells** from mature plant tissues. The unspecialized cells can be transformed with recombinant DNA and then studied in culture, or grown into new plants. There are also methods for making whole transgenic plants without going through the cell culture step. These methods result in plants that carry the recombinant DNA in all their cells, including the germ line cells.

Animal cells grown in lab culture can be used to study expression of human or animal genes, for example for medical purposes. Whole transgenic animals can also be made by inserting new DNA into egg cells.

Inserted DNA is usually integrated into the host chromosome

Cells can be chemically treated to make their outer membranes more permeable, and then mixed with the DNA so that it can diffuse into the cells. Another approach is called electroporation: a short electric shock is used to create temporary pores in the membranes through which the DNA can enter. Viruses can be altered so that they carry recombinant DNA into cells. A common method for transforming plants involves a specific bacterium that inserts DNA into plant cells. Transgenic animals can be produced by injecting recombinant DNA into the nuclei of fertilized eggs. There are even “gene guns” that “shoot” the host cells with tiny metal particles coated with the DNA.

The challenge of inserting new DNA into a cell lies not only in getting it into the host cell, but also in getting it to replicate as the host cell divides. As you saw in [Key Concept 13.3](#), DNA polymerase does not bind to and copy just any sequence. If the new DNA is to be replicated, it must become part of a segment of DNA that contains an origin of replication. Such a DNA molecule is called a **replicon**, or replication unit.

replicon A region of DNA replicated from a single origin of replication.

There are two general ways in which the newly introduced DNA can become part of a replicon within the host cell:

- . It can be spliced into a host chromosome directly.
- . It can enter the host cell as part of a carrier DNA sequence, called a **vector**, and can then either integrate into a host chromosome or be replicated from its own origin of replication.

vector (1) An agent, such as an insect, that carries a pathogen affecting another species.
(2) A plasmid or virus that carries an inserted piece of DNA into a bacterium for cloning purposes in recombinant DNA technology.

Several types of vectors are used to get DNA into cells, some of which we will now describe in more detail.

PLASMIDS AS VECTORS

As we described in [Chapter 12](#), plasmids are small, circular DNA molecules that replicate autonomously in many prokaryotic cells. Several characteristics make plasmids useful as transformation vectors:

Plasmids are relatively small (an *E. coli* plasmid usually has 2,000–6,000 base pairs) and are therefore easy to manipulate in the laboratory.

A plasmid often has one or more restriction enzyme recognition sequences that each occur only once in the plasmid sequence. This makes it easy to insert new DNA into the prokaryotic plasmid before it is used to transform host cells.

Many plasmids contain genes that confer resistance to antibiotics, which can serve as selectable markers.

Plasmids have a bacterial origin of replication (*ori*) and can replicate independently of the host chromosome. It is not uncommon for a bacterial cell to contain hundreds of copies of a recombinant plasmid. For this reason, the power of bacterial transformation to amplify a gene is extraordinary. A 1-liter culture of bacteria harboring the human β -globin gene in a typical plasmid has as many copies of that gene as there are cells in a typical adult human (10^{14}).

A plasmid used as a vector in the laboratory has been extensively altered to include convenient features:

Multiple cloning sites, often with 20 or more unique restriction enzyme sites for cloning purposes (see *HindIII*, *BamHI*, *Sall*, and *PstI* in the diagram below)

An origin of replication that will function in a particular type of host cell (see *ori* in the diagram below)

One or more reporter genes, such as selectable marker genes (see ampicillin resistance and tetracycline resistance in the diagram below)

PLASMID VECTORS FOR PLANTS

An important vector for carrying new DNA into many types of plants is a plasmid found in the bacterium *Agrobacterium tumefaciens*. This bacterium lives in the soil, infects plants, and causes a disease called crown gall, which is characterized by the presence of growths (or tumors) on the plant. *Agrobacterium* contains a plasmid called Ti (for tumor-inducing). When the bacterium infects a plant cell, a region of the Ti plasmid called the T DNA is inserted into the cell, where it becomes incorporated into one of the plant's chromosomes. The Ti plasmid carries the genes needed for this transfer and incorporation of the T DNA. The T DNA carries genes that are expressed by the host cell, causing the growth of tumors and the production of specific sugars that the bacterium uses as sources of energy. Scientists have exploited this remarkable natural "genetic engineer" to insert foreign DNA into the genomes of plants.

When used as a vector for plant transformation, the tumor-inducing and sugar-producing genes on the T DNA are removed and replaced with foreign DNA. The recombinant Ti plasmids are first used to transform *Agrobacterium* cells from which the original Ti plasmids have been removed. Then the *Agrobacterium* cells are used to infect plant cells.

Ti plasmid

Hosts: *Agrobacterium tumefaciens* (plasmid) and infected plants

VIRUSES AS VECTORS

Constraints on plasmid replication limit the size of the new DNA that can be inserted into a plasmid to about 10,000 base pairs. Although many prokaryotic genes may be smaller than this, most eukaryotic genes—with their introns and extensive flanking sequences—are bigger. A vector that accommodates larger DNA inserts is needed for these genes.

Both prokaryotic and eukaryotic viruses are used as vectors for eukaryotic DNA. Bacteriophage λ , which infects *E. coli*, has a DNA genome of about 45,000 base pairs. About 20,000 base pairs are not necessary for the bacteriophage to complete its life cycle (see [Figure](#)

[16.12](#)). These 20,000 base pairs can be deleted and replaced with DNA from another organism, which then gets replicated along with the virus DNA. Because viruses infect cells naturally, they offer a great advantage over plasmids, which often require artificial means to coax them to enter host cells.

Reporter genes help select or identify host cells containing recombinant DNA

Even when a population of host cells is exposed to an appropriate vector, only a small proportion of the cells actually take up the vector. Furthermore, the process of making recombinant DNA is far from perfect. During a ligation reaction, DNA molecules can combine in various ways, many of which do not produce the desired recombinant molecule (see [Figures 18.1](#) and [18.2](#)). Methods have been developed to improve the chance that a desired combination will occur. A simple approach is to cut the vector with two different restriction enzymes that have sites near each other. This produces a molecule with incompatible sticky ends, which is much less likely to simply recircularize during the ligation reaction. The desired insert molecule is cut with the same two enzymes, so that theoretically a functional circular plasmid can be produced only if the vector and insert ligate with one another. Even so, it is often the case that only a small proportion of the ligation products have the desired recombinant sequence.

How can we identify or select the host cells that contain the desired sequence? One way is to use selectable markers, such as those for antibiotic resistance used in early experiments with recombinant DNA (see [Figure 18.1](#)). Selectable markers are one type of **reporter gene**, which is any gene whose expression is easily observed. Here are several types of reporter genes:

reporter gene A genetic marker included in recombinant DNA to indicate the presence of the recombinant DNA in a host cell.

As described earlier, an antibiotic resistance gene in a plasmid or other vector allows the detection of transformed host cells grown in the presence of the selected antibiotic. If the host cells are normally sensitive to the antibiotic, they will grow on medium containing the antibiotic only if they have been transformed by the vector. This approach is used in the selection of transgenic prokaryotic and eukaryotic cells, including those of plants and animals.

The β -galactosidase (*lacZ*) gene in the *E. coli* *lac* operon (see [Figure 16.4](#)) codes for an enzyme that can convert the artificial substrate X-Gal into a bright blue product. Many plasmids contain the *lacZ* gene with a multiple cloning site (i.e., multiple unique restriction enzyme sites where target DNA sequences can be inserted) within its sequence. These plasmids also carry genes for antibiotic resistance. Bacterial colonies containing the plasmid are selected on a solid medium containing the antibiotic. X-Gal is also included in the medium. If a bacterial colony contains a recombinant plasmid that carries the foreign DNA inserted into the *lacZ* gene, it will not make β -galactosidase and the colony will be white. Clones that contain the original plasmid with no insert express the *lacZ* gene and make blue colonies ([Figure 18.3](#)).

DNA taken up by <i>amp^s, lacZ⁻ E. coli</i>	Phenotype for ampicillin	Phenotype for <i>lacZ</i>
None	Sensitive	Not applicable (no growth)
Foreign DNA	Sensitive	Not applicable (no growth)
Plasmid	Resistant	Blue
Recombinant DNA	Resistant	White

Figure 18.3 Selection for Recombinant DNA Selectable marker (reporter) genes are

used by biologists to select for bacteria that have taken up a plasmid. In a typical experiment, most of the bacteria will not take up any DNA. Of those that do, only a small fraction will take up recombinant DNA.

Green fluorescent protein (GFP), which normally occurs in the jellyfish *Aequorea victoria*, emits visible green light when exposed to ultraviolet light. The gene for this protein has been isolated and incorporated into vectors. GFP is now widely used as a reporter gene ([Figure 18.4](#)). GFP has also been modified to emit other colors when exposed to ultraviolet light, and these new variants are widely used by molecular biologists.

Figure 18.4 Green Fluorescent Protein as a Reporter The presence of a plasmid with the gene for green fluorescent protein (GFP) is readily apparent in transgenic cells because the GFP that the cells produce glows under ultraviolet light. This allows the identification of cells carrying a plasmid without the use of selection on antibiotics.

Q: Are cells killed during GFP selection? Why is this important?

18.2 recap

Recombinant DNA can be cloned by using a vector to insert it into a suitable host cell. The vector often has a selectable marker or other reporter gene that gives the host cell a phenotype by which transgenic cells can be identified.

learning outcomes

You should be able to:

- Compare and contrast different types of vectors and reporter genes.
- Outline the steps involved in creating an organism or cell with recombinant DNA, including detection of the cells containing that DNA.

1. Compare the use of a GFP reporter gene with that of an antibiotic resistance gene in detecting cells harboring a foreign DNA sequence.
2. Assume you are using a plasmid vector that contains genes encoding ampicillin resistance and the green fluorescent protein, with a restriction site in the latter gene only. Arrange a–e below to reflect the sequence of steps for inserting a piece of foreign DNA into this plasmid, introducing the recombinant plasmid into bacteria, and verifying that the plasmid and the foreign gene are both present in the bacteria.
 - a. Transform host cells.
 - b. Select colonies for antibiotic resistance.
 - c. Select colonies that do not glow under ultraviolet light.
 - d. Digest vector and foreign DNA with a restriction enzyme.
 - e. Ligate the digested plasmid together with the foreign DNA.

We have described how DNA can be cut with restriction enzymes, inserted into a vector, and introduced into host cells. We have also seen how host cells carrying recombinant DNA can be identified. Now let's consider where the genes or DNA fragments used in these procedures come from.

***connect the concepts** As explained in [Key Concept 19.5](#), stem cells occur in both plants and animals and are cells that are continuously dividing, which can specialize if given the right signals.

18.3 Any Sequence of DNA Can Be Used for Cloning

A major goal of molecular cloning experiments is to learn the functions of the DNA sequences and the proteins they encode. The DNA fragments used in cloning procedures are obtained from several sources that we will describe in this section: random fragments of chromosomes that are maintained as gene libraries, complementary DNA obtained by reverse transcription from mRNA, products of the polymerase chain reaction (PCR), and artificially synthesized or mutated DNA.

focus your learning

A cDNA library represents the RNAs made by a particular cell or tissue type at a particular point in time.

Reverse transcriptase can be used in PCR procedures to create and amplify a specific cDNA sequence such that construction of a library is not necessary.

Artificial DNA can be synthesized using organic chemistry.

DNA for cloning can come from a library

A **genomic library** is a collection of DNA fragments that make up the genome of an organism. Restriction enzyme digestion or other means, such as mechanical shearing, can be used to break chromosomes into smaller pieces. These smaller DNA fragments collectively still constitute a genome ([Figure 18.5A](#)), but the information is now in many smaller “volumes.” Any desired fragment can be inserted into a vector, which is then taken up by a host cell. Proliferation of a single such transformed cell produces a colony of cells, each of which harbors many copies of the same fragment of DNA.

genomic library All of the cloned DNA fragments generated by the breakdown of genomic DNA into smaller segments.
--

Figure 18.5 Constructing Libraries Intact genomic DNA is too large to be introduced into host cells. **(A)** A genomic library can be made by breaking the DNA into small fragments, incorporating the fragments into a vector, and then transforming host cells with the recombinant vectors. Each colony of cells contains many copies of a small part of the genome. **(B)** The many mRNAs in a cell can be copied into cDNAs and a library made from them. The DNA in these colonies can then be isolated for analysis.

If a plasmid vector is used, about 700,000 separate fragments are required to make a library of the human genome. By using bacteriophage λ , which can carry about four times as much DNA as a typical plasmid, the number of “volumes” in the library can be reduced to about 160,000. Although this still seems like a large number, a single petri plate can hold thousands of phage colonies, or plaques, which are easily screened for the presence of a particular DNA sequence by ***hybridization** to an appropriate nucleic acid probe.

cDNA is made from mRNA transcripts

A much smaller DNA library—one that includes only the genes transcribed in a particular tissue at a particular point in time—can be made from **complementary DNA**, or **cDNA** (Figure 18.5B). Making cDNA involves isolating mRNA from cells, then making cDNA copies of that mRNA by

complementary base pairing in a process called [reverse transcription](#). Reverse transcription is catalyzed by the enzyme [reverse transcriptase](#).

complementary DNA (cDNA) DNA formed by reverse transcriptase acting with an RNA template; essential intermediate in the reproduction of retroviruses; used as a tool in recombinant DNA technology; lacks introns.

cDNA See complementary DNA.

reverse transcription Production of DNA using an RNA template.

reverse transcriptase An enzyme that catalyzes the production of DNA (cDNA), using RNA as a template; essential to the reproduction of retroviruses.

A collection of cDNAs from a particular tissue at a particular time in the life cycle of an organism is called a [cDNA library](#). Because mRNAs do not last long in the cytoplasm, the types and amounts of mRNAs present in a cell are a good representation of the transcription rates of all the genes in that cell. So a cDNA library is a “snapshot” that captures the transcription pattern of a set of cells at a given point in time. cDNA libraries have been invaluable for comparing gene expression in different tissues at different stages of development. For example, researchers have found that up to one-third of all the genes of an animal are expressed only during development. cDNA is also a good starting point for cloning eukaryotic genes, because the clones contain only the coding sequences of the genes (the introns having been spliced out; see [Figure 14.7](#)). Also, if a eukaryotic gene is highly expressed in a particular tissue, a cDNA library made from that tissue will be enriched for the gene, making it easier to identify and clone the gene.

cDNA library A collection of complementary DNAs derived from mRNAs of a particular tissue at a particular time in the life cycle of an organism.

Reverse transcriptase can be used in [*PCR](#) procedures to create and amplify a specific cDNA sequence so that it is not necessary to construct a library. In this case, RNA is isolated from an organism or tissue, and reverse transcriptase is used to make cDNA from the RNA. Then PCR is used to amplify a specific sequence directly from the sample of cDNA. This procedure, called [RT-PCR](#), has become an invaluable tool for studying the expression of particular genes in cells and organisms.

RT-PCR A laboratory manipulation of RNA in which the RNA is first incubated with reverse transcriptase (RT) to make cDNA and then the cDNA amplified for analysis by the polymerase chain reaction (PCR).

Synthetic DNA can be made by PCR or by organic chemistry

PCR can begin with as little as 10^{-12} g of DNA (a picogram). Any fragment of DNA can be amplified by PCR as long as appropriate primers are available. DNA replication (by PCR or in a cell) requires not just a template onto which DNA polymerase adds complementary nucleotides, but also a short oligonucleotide primer where replication begins (see [Figure 13.11](#)). If the appropriate primers (two are needed—one for each strand of DNA) are added to template DNA in a PCR reaction, millions of copies of the DNA region between the primers can be produced in just a few hours. This amplified DNA can then be inserted into a vector to create recombinant

DNA and be cloned in host cells.

Artificial DNA can be synthesized using organic chemistry to link nucleotides together in a specified sequence. This process is now fully automated, and a laboratory can make large numbers of short- to medium-length sequences overnight. PCR primers, for example, are made in this way. The synthesis of ***artificial DNA** does not require a template, so DNA with any sequence can be made. This flexibility is useful for creating DNA fragments with desirable characteristics, such as convenient restriction sites or specific mutations. Longer synthetic sequences can be pieced together to construct completely artificial genes that have been designed for specific purposes. For example, a gene might be designed to be highly expressed in a particular cell type, or to encode a highly active enzyme.

18.3 recap

DNA for cloning can be obtained from genomic libraries, cDNA, or artificially synthesized DNA fragments.

learning outcomes

You should be able to:

- Determine which type of library would be most appropriate to construct for a given scenario.
- Predict the expected results in terms of quantities and sequences of cDNA libraries taken from different tissues.
- Show how RT-PCR is used to amplify a specific gene sequence.
- Summarize uses of synthetic DNA.

1. What type of gene library would you use for analyzing each of the following, and why?
 - a. The expression of a gene encoding amylase, a starch hydrolyzing enzyme, in seeds as they germinate
 - b. The sequence of the amylase gene in two different genetic strains of corn (continued)
2. How could RT-PCR be used to compare the mRNA's made by muscle vs. liver tissues?
3. Describe a use for synthetic DNA.
4. Explain why a cDNA library constructed from human brain tissue will likely be both similar to and different from a cDNA library constructed from human pancreatic tissue.

We've explored the various sources of DNA that can be used to make recombinant DNA molecules, and how organisms are transformed with recombinant DNA. We will now turn to some of the ways that recombinant DNA and transformation methods can be used to study the functions of genes and proteins.

***connect the concepts** The technique of nucleic acid hybridization, illustrated in [Figure 14.6](#), involves using a singlestranded nucleic acid probe with a complementary sequence to the target DNA. If the probe forms a double-stranded hybrid molecule, the target DNA fragment has been identified.

***connect the concepts** As illustrated in [Figure 13.19](#), the polymerase chain reaction (PCR) automates replication of a DNA fragment in a test tube. Also called DNA amplification, the

process involves repeatedly synthesizing DNA complementary to a target sequence to make enough DNA for chemical analysis and genetic manipulations.

***connect the concepts** Plasmids containing synthetic transposon DNA have been used to transfect host cells to inactivate genes one by one and give insight into the minimal genome. See [Key Concept 17.2](#).

18.4 Several Tools Are Used to TO Modify DNA and Study Its Function

So far in this chapter we have seen how recombinant DNA is made and how organisms are transformed with recombinant DNA. In this section we will examine several additional techniques for studying DNA. These approaches include expression of genes in different biological systems, mutagenesis, methods to block gene expression, and DNA microarrays to analyze large numbers of nucleotide sequences.

focus your learning

Microarrays can be used to examine patterns of gene expression simultaneously across the genome.

RNA interference can be used to block specific gene expression, usually at the translational level.

CRISPR technology can be used to alter and inactivate specific genes.

Gene expression can be modulated by DNA technology

DNA can be manipulated to be expressed in a different location or at a different rate.

Researchers have learned a lot about gene expression and function by exploring questions such as these:

What happens when a gene is moved to a new location? A scientist may want to study a gene's function and how it interacts with other genes by expressing the gene in a different organism—for example, by inserting a human gene into a bacterium, or a bacterial gene into a plant.

Researchers have learned that expression of a transplanted gene requires a promoter and other regulatory sequences from the host organism: a bacterial promoter will not function in a plant cell, for example. The coding region of the gene of interest needs to be inserted between a promoter and a transcription termination sequence derived from the host organism, or from an organism that uses similar mechanisms for gene regulation.

What happens when the rate of expression of a gene is changed? Researchers have learned that a gene can be overexpressed in cells where it is normally expressed at lower levels, so that much more of its protein product is made. Overexpression is achieved by inserting a gene adjacent to a promoter that is very active in a cell, and then cloning the recombinant promoter–gene combination in a host cell.

Many thousands of experiments have shed light on the functions of genes and their protein products. One example involves a genetic system that probably evolved to prevent inbreeding in plants. Most plants produce flowers with both male and female parts, but many plant species are self-incompatible; they cannot self-pollinate (see [Key Concepts 28.3](#) and [37.1](#)). Their flowers produce a protein that recognizes “self” pollen, and prevents the pollen from fertilizing egg cells in the same flower (see [Figure 37.4](#)). Genetic crosses suggested that a particular multi-allelic gene, called the S gene, was responsible for self-incompatibility. Definitive proof was obtained when plants were transformed with recombinant DNA containing an S allele different from their own S alleles. The transgenic plants rejected not only their own pollen but also pollen from flowers that naturally carried the foreign S allele.

DNA mutations can be created in the laboratory

Mutations that occur in nature have been important in demonstrating cause-and-effect relationships for a specific gene. However, mutations in nature are rare events. DNA technology allows us to explore the consequences of various mutations by creating them artificially. Synthetic DNA can be made with any desired sequence, and its effect on the organism can be observed when the mutant DNA is expressed in host cells.

Genes can be inactivated and changed by CRISPR technology

As we have just discussed, a gene can be studied by expressing it in cells where it is not normally expressed or by expressing it at higher than normal levels. Another way to study a gene is to inactivate it, so that it is not transcribed and translated into a functional protein, or to change its DNA sequence so that an altered gene product is made. CRISPR technology offers a powerful new approach for “gene editing” (adding, disrupting, or changing the sequence of specific genes) and gene regulation ([Figure 18.6](#)). As with many other tools of biotechnology, the method emulates a mechanism found in nature, one that some bacteria and many archaea use to defend themselves against viral infections. The genomes of these species have many short (24–48 bp) palindromic sequences of DNA (see [Key Concept 18.1](#)), with unique 24-bp spacer DNA in between, which are known by the acronym [CRISPR](#) (clustered regularly interspaced short *palindromic repeat* sequences). While the CRISPR sequence is the same for each repeating unit, the spacers are different. Each spacer is a fragment of DNA from a virus that previously infected the cell but did not end up destroying its host. The spacer sequences thus provide “genetic mug shots” that inform the cell carrying them what viruses to look out for. When a virus carrying a sequence similar to the spacer DNA injects its DNA into the cell, the unit—CRISPR and spacer—is transcribed into RNA, to which a second short RNA attaches. This RNA complex then performs the following two functions:

research tools

1 Bacteria and archaea have many CRISPR sequences separated by unique spacers that are remnants of prior virus invaders.

2 When a virus with a target unique sequence invades the cell, an RNA is made that includes the CRISPR sequence. Another RNA is added. CAS9, a nuclease, binds to the RNA.

3 The complex binds to the unique target on the invading viral genome. The nuclease cuts the viral DNA, inactivating it.

4 The nuclease cuts the viral DNA, inactivating it and preventing viral reproduction in the bacterial cell.

5 An RNA can be made in the lab that has any desired target sequence and the CAS9 binding sequence, so any gene can be inactivated.

6 The RNA is introduced into the cell with the target DNA. When CAS9 in the cells cuts the target DNA, the cell repairs it. A short repair sequence with a specific alteration can assist the repair, introducing a specific mutation.

Figure 18.6 Inactivating or Mutating a Gene by CRISPR A molecular system used by bacteria to combat invading viruses has been adapted to inactivate or mutate any gene.

Activity 18.1 **CRISPR Simulation** www.Life11e.com/ac18.1

CRISPR In archaea, clustered regularly interspaced short palindromic sequences in DNA that are adjacent to sequences from invading viruses. When the two sequences are transcribed, the RNA binds a complementary RNA that binds a nuclease, Cas9, that can cleave and inactivate the genome of the invading virus. This mechanism can be adapted for inactivating and mutating any gene.

- . Because the spacer sequence is complementary to part of the viral genome, it attaches to it by base pairing.
- . The complex binds a protein called CAS9, which is a nuclease that cuts the invading viral DNA, destroying its ability to produce new viruses and thereby protecting the host cell.

Therefore any cell that was once infected by a virus has the “memory” of that infection encoded in its genome, and those of all cells that are produced from it.

Once this natural immune system was described, it occurred to Emmanuelle Charpentier at Umeå University in Sweden and Jennifer Doudna at the University of California, Berkeley that it might be adapted to cut any DNA at a specific location: all that was needed was the RNA complementary to the target (a “guide” RNA) and the CAS9 enzyme. Tens of thousands of unique guide RNAs are now available commercially, each targeted to a specific gene in a specific organism, prokaryotic or eukaryotic, making possible a diversity of studies of inactivated genes and exploration of a multitude of “What if?” questions.

The simplicity of CRISPR technology to inactivate genes holds great promise. To give just one early example, a fungal disease called powdery mildew can devastate a wheat crop. Many wheat varieties have a gene whose expression inhibits wheat’s natural defenses against this disease, so the only way to control the disease is through heavy application of fungicides. Scientists in China used CRISPR technology to inactivate this gene, so that natural resistance is favored.

CRISPR technology can be used to create specific mutations. When CAS9 cuts target DNA in a living cell, the cell attempts to repair the damage (see [Figure 13.18](#)). Often this repair is imperfect, so that the rejoined DNA has a mutation. Biologists can specify the mutation by synthesizing a short DNA sequence complementary to the region at the break so that the new sequence will have a specific alteration.

Perhaps more dramatic than the ability to induce mutations is the possibility of correcting mutations, particularly those that cause disease. For example, the disease cystic fibrosis is caused by mutation of a membrane transport protein. Scientists in the Netherlands have used CRISPR to correct the mutation in cells from patients with this disease. While this is not a cure (the corrected gene would have to function in many tissues), the possibility arises that the mutated gene could be corrected in germ line cells, such as those of an early embryo. However, the ease with which the human germ line genome can be altered using CRISPR technology has elicited ethical and legal concerns. In some countries altering the germ line in a human is illegal.

Complementary RNA can prevent the expression of specific genes

Another way to study the expression of a specific gene is to knock it out by blocking the translation of its mRNA. The process developed for knocking out genes is yet another example of scientists imitating nature. As described in [Key Concept 16.5](#), gene expression is sometimes regulated by the production of double-stranded RNA molecules that are processed to produce short, single-stranded microRNA (miRNA). These miRNAs are complementary to specific mRNA sequences (see [Figure 16.18A](#)), and when they bind to their target mRNAs, they inhibit translation. The hybrid mRNA molecules consisting of miRNA and the target mRNA tend to break down rapidly in the cytoplasm. Although the target gene continues to be transcribed, translation does not take place. Scientists have applied the idea of hybrid RNAs in developing methods for blocking the expression of particular genes ([Figure 18.7](#)). An organism can be transformed to produce mRNAs that are complementary to and thus bind to specific endogenous mRNAs, which prevents expression of the endogenous mRNA. Alternatively, cells can be injected with synthetic complementary sequences (see [Figure 18.7B](#)). The complementary single-stranded RNA sequence is called **antisense RNA** because it binds by base pairing to the “sense” bases on the mRNA.

(A) Normal translation

Figure 18.7 Using Antisense RNA and siRNA to Block Translation of mRNA (A) Normally an mRNA is translated to produce a protein. Translation of a target mRNA can be prevented with **(B)** an antisense RNA or **(C)** a small interfering RNA (siRNA) that is complementary to the target mRNA.

antisense RNA A single-stranded RNA molecule complementary to, and thus targeted against, an mRNA of interest to block its translation.

It may be possible to make antisense drugs to treat diseases that involve gene expression. For example, people with the genetic disease familial hypercholesterolemia are unable to break down cholesterol in the blood and accumulate fat deposits in blood vessels (as was the case with Janet whose story opened this chapter). Their excess cholesterol is transported in blood as part of a lipoprotein. Mipomersen is an antisense RNA directed against the translation of the mRNA for the “protein” part of this lipoprotein. When people with hypercholesterolemia take this drug, the level of the lipoprotein is reduced and so is the level of cholesterol in the bloodstream. Fat accumulation in blood vessels is lowered.

A technique related to antisense RNA takes advantage of [RNA interference \(RNAi\)](#), a natural mechanism for inhibiting mRNA translation that involves small interfering RNA (siRNA; see [Figure 16.18B](#)). siRNAs bind to complementary regions on their target mRNAs, which are then degraded. Since the discovery of RNAi in the late 1990s, scientists have synthesized artificial double-stranded siRNAs to inhibit the expression of known genes (see [Figure 18.7C](#)). Because these double-stranded siRNAs are more stable than antisense RNAs, the use of siRNAs is the preferred approach for blocking translation. An RNAi-based therapy has been

developed to treat macular degeneration, an eye disease that results in near-blindness when blood vessels proliferate in the eye. The signaling molecule that stimulates vessel proliferation is a growth factor. An siRNA that targets this growth factor's mRNA shows promise in stopping and even reversing the progress of the disease. Although medical applications for RNAi are mostly at the experimental stage, antisense RNA and RNAi have been widely used to test cause-and-effect relationships in biological research.

RNA interference (RNAi) A mechanism for reducing mRNA translation whereby a double-stranded RNA, made by the cell or synthetically, is processed into a small, single-stranded RNA, whose binding to a target mRNA results in the latter's breakdown.

DNA microarrays reveal RNA expression patterns

The science of genomics faces two major quantitative challenges. First, there are very large numbers of genes in eukaryotic genomes. Second, there are myriad distinct patterns of gene expression in different tissues at different times. For example, the cells of a skin cancer at its early stage may have a unique mRNA “fingerprint” that differs from those of normal skin cells and cells from a more advanced skin cancer. In such a case, the pattern of gene expression could provide invaluable information to a clinician trying to characterize a patient's tumor (see below).

To identify distinct patterns of gene expression, scientists could isolate mRNA from cells and measure the amount of each gene's mRNA one gene at a time by hybridization or RT-PCR. But that would involve many steps and take a very long time. It is far simpler to do these hybridizations all in one step, and that is made possible with [DNA microarray](#) technology.

DNA microarray A small glass or plastic square onto which thousands of single-stranded DNA sequences are fixed so that hybridization of cell-derived RNA or DNA to the target sequences can be performed.

DNA microarrays (“gene chips”) contain a series of DNA sequences attached to a glass slide in a precise order. The slide is divided into a grid of microscopic spots, or “wells.” Each spot contains thousands of copies of a particular oligonucleotide of 20 or more bases. A computer controls the addition of these oligonucleotide sequences in a predetermined pattern. Each oligonucleotide can hybridize with only one DNA or RNA sequence and thus is a unique identifier of a gene. Many thousands of different oligonucleotides can be placed on a single microarray to detect genetic variation. For example, DNA with a mutant allele may not hybridize to a target wild-type gene fragment on an array. Since arrays can contain thousands of gene fragments, mutations in many genes can be screened for at the same time. With different patterns of gene expression, differences in mRNAs in tissues such as breast cancers can be detected by microarrays ([Figure 18.8](#)).

Figure 18.8 Using DNA Microarrays for Clinical Decision-Making The pattern of expression of many genes in tumor tissues (the pattern of colored spots) indicates whether breast cancer is likely to recur. Actual arrays have more spots than shown here.

18.4 recap

Researchers can study the function of a gene by expressing it in cells where it is not normally expressed, by overexpressing it, or by inactivating the gene in a living organism. CRISPR technology allows selective inactivation or alteration of gene sequences. Antisense RNAs and siRNAs prevent gene expression by selectively blocking mRNA translation. DNA microarrays allow the simultaneous analysis of many different mRNA transcripts.

learning outcomes

You should be able to:

- Outline experiments that use RNA interference to develop new drugs for diseases.
- Describe how microarrays are used to examine patterns of gene expression

1. In some bladder cancers, the gene for the cell signaling molecules, *Ras*, is mutated, resulting in an altered protein that stimulates cell division. How might siRNA technology be

used to develop a drug to treat this disease? Would the drug be specific for the cancer?

2. As pea seeds germinate, the embryo changes which genes are expressed. How would you use microarrays to analyze this?
3. Both antisense RNA and CRISPR technology can be used to block the expression of specific genes. What is the additional advantage of CRISPR?

Now that you've seen how DNA can be fragmented, recombined, manipulated, and put back into living organisms, let's see some examples of how these techniques are used to make useful products.

18.5 DNA Can Be Manipulated for Human Benefit

Biotechnology is the use of cells or whole living organisms to produce materials useful to people, such as foods, medicines, and chemicals. People have been using various forms of biotechnology for a long time. For example, the use of yeasts to brew beer and wine dates back at least 8,000 years, and the use of bacterial cultures to make cheese and yogurt is a technique many centuries old. For a long time people exploited these biochemical transformations without being aware of the organisms and genes involved. Today with recombinant DNA techniques, almost any gene can be inserted into bacteria, yeasts, mammalian cells, plant cells, or even whole organisms, inducing them to make a gene product in large amounts.

biotechnology The use of living cells or organisms to produce materials useful to humans.

focus your learning

Expression vectors are constructed to ensure the expression of foreign genes in host cells.

Modern recombinant DNA technology has significant advantages over traditional breeding methods used in agriculture.

The use of biotechnology has ethical and environmental ramifications.

Cells can be turned into factories for a desired protein

If a eukaryotic gene is inserted into a typical bacterial plasmid and used to transform *E. coli*, little if any of the gene product will be made unless other key prokaryotic DNA sequences are included with the gene. A bacterial promoter, a signal for transcription termination, and a special sequence that is necessary for binding of bacterial ribosomes to the mRNA must all be included in the transformation vector if the gene is to be expressed in a bacterial cell.

To ensure expression of foreign genes by host cells, scientists make **expression vectors** having not only the characteristics of cloning vectors, but the extra sequences needed for the foreign gene (also called a transgene) to be expressed in the host cell. The insertion of an expression vector for a bacterial host is illustrated in **Figure 18.9**. An expression vector for a eukaryotic host would require the poly A–addition sequence for mRNA stability and a promoter that contains all the elements needed for expression in a eukaryotic cell.

expression vector A DNA vector, such as a plasmid, that carries a DNA sequence for the expression of an inserted gene into mRNA and protein in a host cell.

Figure 18.9 Expression of a Transgene in a Host Cell Produces Large Amounts of Its Protein Product To be expressed in *E. coli*, a gene derived from a eukaryote requires bacterial sequences for transcription initiation (promoter), transcription termination, and ribosome binding. Expression vectors contain these additional sequences, enabling the eukaryotic protein to be synthesized in the prokaryotic cell.

 Activity 18.2 Expression Vectors www.Life11e.com/ac18.2

An expression vector can be designed to deliver transgenes to any class of prokaryotic or eukaryotic host and may include additional features:

An *inducible promoter*, which responds to a specific signal, can be included. For example, a promoter that responds to hormonal stimulation can be used so that the transgene will be expressed at high levels only when the hormone is added.

A *tissue-specific promoter*, which is expressed only in a certain tissue at a certain time, can be used if localized expression is desired. For example, many seed proteins are expressed only in the plant embryo. Coupling a transgene to a seed-specific promoter will allow the gene to be expressed only in seeds.

Signal sequences can be added so that the gene product is directed to an appropriate destination. For example, when a protein is made by yeast or bacterial cells in a liquid medium, it is economical to include a signal directing the protein to be secreted into the extracellular

medium for easier recovery.

Medically useful proteins can be made using biotechnology

Biotechnology produces many medically useful products ([Table 18.1](#)), and more are in various stages of development. A good illustration of a medical application of biotechnology is the manufacture of tissue plasminogen activator (TPA) discussed in the opening of this chapter. As noted there, TPA is a human protein involved in hydrolysis of blood clots, and can be used to remove clots that block blood flow in a stroke.

table 18.1 Some Medically Useful Products of Biotechnology	
Product	Use
Colony-stimulating factor	Stimulates production of white blood cells in patients with cancer and AIDS
Erythropoietin	Prevents anemia in patients undergoing kidney dialysis and cancer therapy
Factor VIII	Replaces clotting factor missing in patients with hemophilia A
Growth hormone	Replaces missing hormone in people of short stature
Insulin	Stimulates glucose uptake from blood in people with insulindependent (type I) diabetes
Platelet-derived growth factor	Stimulates wound healing
Tissue plasminogen activator	Dissolves blood clots after heart attacks and strokes
Vaccine proteins: Hepatitis B, herpes, influenza, Lyme disease, meningitis, pertussis, etc.	Prevent and treat infectious diseases

To make TPA in amounts needed for clinical use, scientists first isolated the TPA gene by taking the mRNA for TPA and making a cDNA copy in the lab. The cDNA was then inserted into an expression vector and used to transform mammalian cells (**Investigating Life: Producing TPA**). The transgenic cells made the protein in quantity, and it soon became available commercially. As you saw at the start of the chapter, the drug has been a success in treating strokes.

Another way of making medically useful products in large amounts is [pharming](#): the production of pharmaceuticals in farm animals or plants. For example, a gene encoding a useful protein might be placed next to the promoter of the gene that encodes lactoglobulin, an abundant milk protein. Transgenic animals carrying this recombinant DNA will secrete large amounts of the foreign protein into their milk. These natural “bioreactors” can produce abundant supplies of the protein, which can be separated easily from the other components of the milk ([Figure 18.10](#)).

pharming The use of genetically modified animals to produce medically useful products in their milk.

Figure 18.10 Pharming An expression vector carrying a desired gene can be put into an animal egg, which is implanted into a surrogate mother. The transgenic offspring produces the new protein in its milk. The milk is easily harvested and the protein isolated, purified, and made clinically available to patients.

Q: A drug that is an enzyme from bacteria has been developed to treat the genetic disorder Gaucher's disease, using carrot cells in tissue culture. The targeted enzyme functions inside the lysosome. In addition to inserting the gene for the enzyme into carrot cells, what other DNA sequences need to be inserted into the plant cells so that the enzyme will be functional in humans

DNA manipulation is changing agriculture

The cultivation of plants and the husbandry of animals provide the world's oldest examples of biotechnology, dating back more than 10,000 years. Over the centuries, people have adapted

crops and farm animals to their needs, producing organisms with desirable characteristics such as large seeds, high fat content in milk, or resistance to disease.

Until recently, the most common way to improve crop plants and farm animals was to identify individuals with desirable phenotypes that existed as a result of natural variation. Through many deliberate *crosses—a process called selective breeding—the genes responsible for the desirable trait could be introduced into a widely used variety or breed of that organism.

Despite some spectacular successes—among them the breeding of high-yielding varieties of wheat, rice, and hybrid corn—such deliberate crossing can be a hit-or-miss affair. Many desirable traits are controlled by multiple genes, and it is hard to predict the results of a cross or to maintain a prized combination as a true-breeding variety year after year, especially because in sexual reproduction combinations of desirable genes are quickly separated by meiosis. Furthermore, traditional breeding takes a long time: many plants and animals take years to reach maturity and then can reproduce only once or twice a year—a far cry from the rapid reproduction of bacteria.

Here are just some of the advantages that modern recombinant DNA technology offers over traditional methods of breeding:

The ability to identify specific genes. The development of genetic markers allows breeders to select for specific desirable genes, making the breeding process more precise and rapid.

The ability to introduce any gene from any organism into a plant or animal species. This ability, combined with mutagenesis techniques, vastly expands the range of possible new traits.

The ability to generate new organisms quickly. Manipulating cells in the laboratory and regenerating a whole plant or animal by cloning is much faster than traditional breeding.

Producing TPA

experiment

For a protein such as TPA to become useful in the clinic, the expression of recombinant DNA (in this case, the TPA gene coupled to an active promoter) in cells must result in a large amount of the protein. The protein is then purified and used to treat patients with a stroke, by catalyzing the dissolution of a blood clot in an artery leading to the brain.

Original Paper: Collen, D. et al. 1984. Biological properties of human tissue-type plasminogen activator obtained by expression of recombinant DNA in mammalian cells. *Journal of Pharmacology and Experimental Therapeutics* 231: 146–152.

HYPOTHESIS▶ A clinically useful TPA can be made by recombinant DNA technology.

METHOD

CONCLUSION▶ TPA made by biotechnology can be used to treat patients.

work with the data

It is essential that a purified molecule made by biotechnology have the desired biological properties. In the case of TPA, the goal was to mimic the properties of the natural clot-dissolving molecule. Désiré Collen, a physician-scientist in Belgium, led an international team that compared laboratory-made TPA with the natural molecule made by human cells. They performed two types of experiments, one on clots suspended in human blood in the lab, and the other on clots that had developed in rabbits. The team also investigated the time course of clot dissolution and the dose of TPA needed for the effect.

QUESTIONS

- Human blood clots were prepared in the lab using a radioactively labeled clotting molecule. Dissolution of the clot resulted in the radioactive molecules becoming hydrolysis products (monomers), so comparing soluble to insoluble radioactivity was a measure of clot dissolution. **Table A** shows the results of clot dissolution over time after injection with natural TPA, TPA made by biotechnology, and a control injection without TPA. Plot the data in a graph of percent clot dissolution over time. What can you conclude about the experiment?
- To determine whether lab-made TPA could dissolve clots in the mammalian blood system, clots were induced in a large vein in rabbits. After 20 h, either natural or lab-made TPA was injected at the clot region and the dissolution of the clot measured 4 h later. The results are shown in **Table B**. What can you conclude about this experiment? The results show the SEM (standard error of the mean) for the data. How would you use a statistical test to examine the significance, if any, between the two treatment groups and compare them with the control?

Table A

Time (h)	Percent clot dissolution		
	No TPA (Control)	Natural TPA	Lab-made TPA
1	0	4	5
2	0	10	20
3	1	20	35
4	1	35	55
5	2	50	65

Table B

Dose of TPA (units)	Percent clot dissolution (SEM)	
	Natural TPA	Lab-made TPA
0 (control)	14.3 (1.4)	14.3 (1.4)
12,000	19.8 (5.4)	22.3 (6.0)
24,000	24.5 (7.9)	30.6 (0.8)
48,000	38.9 (4.8)	49.3 (9.7)
96,000	66.0 (6.3)	75.4 (3.9)

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Consequently, recombinant DNA technology has found many applications in agriculture (**Table 18.2**). We will describe a few examples to demonstrate the approaches that plant scientists have used to improve crop plants.

table 18.2 Agricultural Applications of Biotechnology under Development

Goal	Technology/genes
Improving the environmental adaptations of plants	Genes for drought tolerance, salt tolerance
Improving nutritional traits	High-lysine seeds; β -carotene in rice
Improving crops after harvest	Delay of fruit ripening; sweeter vegetables
Using plants as bioreactors	Plastics, oils, and drugs produced in plants

PLANTS THAT MAKE THEIR OWN INSECTICIDES

Plants are subject to infections by viruses, bacteria, and fungi, but probably the most important crop pests are herbivorous insects. From the locusts of biblical (and modern) times to the cotton boll weevil, insects have continually eaten the crops people grow.

The development of insecticides has improved the situation, but insecticides have their own problems. Many, including the organo-phosphates, are relatively nonspecific and kill beneficial insects in the broader ecosystem as well as crop pests. Some pesticides even have toxic effects on other groups of organisms, including people. What's more, many insecticides persist in the environment for a long time.

Some bacteria protect themselves by producing proteins that can kill insects. For example, the bacterium *Bacillus thuringiensis* produces a protein that is toxic to the insect larvae that prey on it.

Bacillus thuringiensis

The toxicity of this protein to insects is 80,000 times greater than that of a typical commercial insecticide. When a hapless larva eats the bacteria, the toxin becomes activated and binds specifically to the insect's gut, producing holes and killing the insect. Dried preparations of *B. thuringiensis* have been sold for decades as safe insecticides that break down rapidly in the environment. But the biodegradation of these preparations is their limitation, because it means that the dried bacteria must be applied repeatedly during the growing season.

A longer-acting approach is to have the crop plants themselves make the toxin, and this is exactly what plant scientists have done. The toxin gene from *B. thuringiensis* has been isolated, cloned, and extensively modified by the addition of a plant promoter and other regulatory sequences. Transgenic corn, cotton, soybeans, tomatoes, and other crops are now being grown successfully with this added gene. Farmers growing these transgenic crops use less of other pesticides.

CROPS THAT ARE RESISTANT TO HERBICIDES

Herbivorous insects are not the only threat to agriculture. Weeds may grow in fields and compete with crop plants for water and soil nutrients. Glyphosate is a widely used and effective herbicide, or weed killer, that works only on plants. It inhibits an enzyme system in the chloroplast that is involved in the synthesis of amino acids. Glyphosate is a broad-spectrum herbicide that kills most weeds, but unfortunately it also kills crop plants. One solution to this problem is to use it to rid a field of weeds before the crop plants start to grow. But as any gardener knows, when the crop begins to grow, the weeds reappear. If the crop were not affected by the herbicide, the herbicide could be applied to the field at any time without harming the crop.

Scientists have used expression vectors to make plants that synthesize a different form of the target enzyme for glyphosate that is unaffected by the herbicide. The gene for this enzyme has been inserted into corn, cotton, and soybean plants, making them resistant to glyphosate. This

technology has expanded rapidly, and a large proportion of cotton and soybean plants now carry this gene.

GRAINS WITH IMPROVED NUTRITIONAL CHARACTERISTICS

To remain healthy, humans must consume adequate amounts of β -carotene, which the body converts into vitamin A. About 400 million people worldwide suffer from vitamin A deficiency, which makes them susceptible to infections and blindness. One reason is that rice grains, which do not contain β -carotene, make up a large part of their diets. Rice grains lack the two-enzyme biochemical pathway that synthesizes β -carotene.

Plant biologists Ingo Potrykus and Peter Beyer isolated one of the genes for the β -carotene pathway from the bacterium *Erwinia uredovora* and the other from daffodil plants. They added a promoter and other signals for expression in the developing rice grain and then transformed rice plants with the two genes. The resulting rice plants produce grains that look yellow because of their high β -carotene content. A newer variety with a corn gene replacing the one from daffodils makes even more β -carotene and is golden in color ([Figure 18.11](#)). A daily intake of about 150 g of this cooked rice can supply all the β -carotene a person needs. This new transgenic strain has been crossed with strains adapted for various local environments, in the hope of improving the diets of millions of people.

Figure 18.11 Transgenic Rice Rich in β -Carotene Middle and right: The grains from these transgenic rice strains are colored because they make the pigment β -carotene, which is converted to vitamin A in the human body. Left: Wild-type rice grains do not contain β -carotene.

CROPS THAT ADAPT TO THE ENVIRONMENT

Agriculture depends on ecological management—tailoring the environment to the needs of crop plants and animals. A farm field is an unnatural, human-designed system that must be carefully managed to maintain optimal conditions for crop growth. For example, excessive irrigation can cause increases in [*soil salinity](#). The Fertile Crescent, the region between the Tigris and Euphrates rivers in the Middle East where agriculture probably originated 10,000 years ago, is no longer fertile. It is now a desert, largely because the soil has a high salt concentration. Few plants can grow on salty soils, partly because of osmotic effects that result in wilting, and partly because excess salt ions are toxic to plant cells.

Some plants can tolerate salty soils because they have a protein that transports Na^+ ions out of the cytoplasm and into the vacuole, where the ions can accumulate without harming plant growth (see [Key Concept 5.3](#) for a description of the plant vacuole). Scientists developed a highly active version of the gene for this transporter protein and used it to transform crop plants that are less tolerant to salt, including rapeseed, wheat, and tomatoes. When this gene was added to tomato plants, they grew in water that was four times as salty as the typical lethal level ([Figure 18.12](#)). This finding raises the prospect of growing crops on what were previously unproductive soils.

(A)

(B)

Figure 18.12 Salt-Tolerant Tomato Plants Transgenic plants containing a gene for salt tolerance thrive in salty water **(A)**, whereas plants without the transgene die **(B)**. This technology may allow crops to be grown on salty soils.

Perhaps the most spectacular transgenic crop developed so far is a strain of rice that is resistant to both salt stress (using the gene above) and drought stress (using a gene from a bacterium) and has the ability to grow on nitrogen-deficient soils (using a gene from barley). This triply-tolerant rice is undergoing field tests.

These examples illustrate what could become a fundamental shift in the relationship between crop plants and the environment. *Instead of manipulating the environment to suit the plant, biotechnology may allow us to adapt the plant to the environment.* As a result, some of the negative effects of agriculture, such as water pollution, could be lessened.

Synthetic biology can create living factories for new products

In [Key Concept 17.2](#), you learned how inactivating genes one at a time can help define which genes are necessary for life in a particular organism (the minimal genome) and which ones confer special properties to the organism. One goal of this research is to design new life forms with specific purposes. That is, new genes could be added to the minimal genome. An important step toward this goal has been the laboratory synthesis of an artificial genome and its insertion into bacterial cells. This was first done using the bacterium *Mycoplasma mycoides*. The artificial genome was then inserted into empty cells of a related species, *Mycoplasma capricolum*, whose own DNA had been hydrolyzed. The new DNA directed the cell to perform the biochemical functions of life, including reproduction ([Figure 18.13](#)).

Figure 18.13 Synthetic Cells These cells of *Mycoplasma mycoides* contain a synthetic genome.

Q: What are some potential uses of synthetic cells

The aims of synthetic biology are bold: to create bacteria or other organisms with new functions, such as producing hydrocarbons for fuel, new drugs for medicine, bacteria that make plastics and other polymers, and so on. But before these functions can be added to the genome, the genes involved must be clearly described, including regulatory genes and sequences such as promoters that function in host cells. Thousands of such genes and chemicals that regulate their expression have now been associated with many known gene functions. For example, a single function (bacteria making ammonium sulfate that could be used for fertilizer in farming) requires more than 70 genes.

There is public concern about biotechnology

Concerns have been raised about the wisdom and safety of genetically modifying crops and other organisms. These concerns are centered on three claims:

- . Genetic manipulation is an unnatural interference with nature.
- . Genetically altered foods are unsafe to eat.
- . Genetically altered crop plants are dangerous to the environment.

Advocates of biotechnology tend to agree with the first claim. However, they point out that all crops are unnatural in the sense that they come from artificially bred plants growing in a manipulated environment (a farmer's field). Recombinant DNA technology just adds another level of sophistication to these technologies. Synthetic biology, however, takes genetic manipulation dramatically further.

To counter concern about whether genetically engineered crops are safe for human consumption, biotechnology advocates point out that only single genes are added and that these genes are specific for plant function. For example, the *B. thuringiensis* toxin produced by transgenic plants has no effect on people. However, as plant biotechnology moves from adding genes that improve plant growth to adding genes that affect human biology, such concerns will become more pressing.

Various negative environmental impacts have been envisaged. The concern has been raised, for example, about the possible "escape" of transgenes from crops to other species. If the gene for herbicide resistance, for example, were inadvertently transferred from a crop plant to a closely related weed, that weed could thrive in herbicide-treated areas. Increased use of herbicides has already resulted in the selection of weeds with naturally occurring mutations that make them resistant to that herbicide. Widespread use of glyphosate on fields of glyphosate-resistant crops, for example, has resulted in the selection of rare mutations in weeds that make them resistant to glyphosate. Field-evolved resistance now occurs in half the major weed species examined.

Because of the potential benefits of biotechnology, scientists believe that it is wise to proceed, albeit with caution.

18.5 recap

Expression vectors maximize the expression of transgenes inserted into host cells. Biotechnology has been used to produce medicines and to develop transgenic plants with improved agricultural and nutritional characteristics.

learning outcomes

You should be able to:

- Describe the essential features of expression vectors.
- Summarize the advantages of modern recombinant DNA technology over selective breeding in agriculture.
- Evaluate the ethical and environmental concerns posed by specific uses of biotechnology, taking into account the risks and rewards that would likely come from their use.

1. What are the essential features of expression vectors?
2. Compared with traditional methods, what are the advantages of using biotechnology for plant breeding?
3. After Cohen and Boyer did their experiment (see [Key Concept 18.1](#)), a group of scientists, public health officials, and bioethicists held a conference and agreed to a temporary moratorium on most recombinant DNA research. What do you think were the concerns that led to the moratorium? How was safety assured so that the moratorium was lifted?

▶ investigatinglife

QA How is biotechnology changing medicine?

What are the limitations of treating patients with the clot-busting drug TPA, made by biotechnology? We opened this chapter with the story of Janet's stroke, pointing out how important it is to treat stroke patients quickly. An analysis published in 2014 of many studies done in the 20 years since TPA was first clinically used showed that the probability of having no significant disability is 75 percent higher in people who get TPA within 3 hours of stroke onset compared with people who don't get TPA. This benefit is reduced if a patient gets the drug later, and is almost nonexistent at 6 hours poststroke.

One of the problems that arose when TPA treatments were initially administered was that the drug tended to break down rapidly in the bloodstream after injection. Biotechnologists solved this problem by altering the TPA gene slightly so that the protein gets glycosylated (adding sugars), which leads to a longer lifetime in the bloodstream. As other drugs are developed by biotechnology, the TPA story is being repeated: initial success, problems with the chemistry, and then modification.

While the commercial production of drugs by DNA biotechnology has had some successes, the examples are relatively limited and certainly not as notable as those in traditional biotechnology, where bacteria and other microbes are manipulated by their environment to make large amounts of molecules, such as antibiotics. However, as we described, DNA manipulation technologies such as microarrays and CRISPR hold great promise to profoundly change medical diagnosis and treatment.

Future directions
